- Antibodies to HBV. A positive result means that the person has either been effectively vaccinated against HBV or has been infected at some point in the past and has recovered.
- Surface antigen of the hepatitis B virus (HBsAg). The surface antigen is the outer coating of the virus. A positive HBsAg test means that the patient is currently infected and can pass on the virus to others.
- Hepatitis B DNA, which measures the levels of virus in the patient's blood.

Patients with chronic active hepatitis B may be given a computed tomography (CT) scan or ultrasound imaging of the liver to determine whether the liver has been damaged by the infection. The doctor may also perform a liver biopsy. This test involves inserting a long, hollow needle into the patient's liver through the abdomen and withdrawing a small amount of tissue for examination under a microscope.

Treatment

Few treatment options are available for chronic hepatitis B. If the patient has no symptoms and little sign of liver damage, the doctor may suggest monitoring the levels of HBV in the patient's blood periodically rather than starting drug treatment right away.

Vaccine and drugs

For patients who know that they have been exposed to HBV, the administration of three shots of the HBV vaccine is used to prevent them from developing an active infection. Those who have already developed symptoms of the acute form of the disease may be given intravenous fluids to prevent dehydration or anti-nausea medications to stop vomiting.

Several drugs have been approved in the United States to treat chronic hepatitis B in adults, but they do not work in all patients and may produce severe side effects. These drugs include adefovir dipivoxil (Hepsera), alpha interferon (Intron A), pegylated interferon (Pegasys), entecavir (Baraclude), telbivudine (Telzeka), tenofovir (Viread), and lamivudine (Zeffix

WWW.BOOKBAZ.IR

or Epivir-HBV). The two interferons are given by injection, and the other five drugs are taken by mouth in pill form. Most doctors will wait until the patient's liver function begins to worsen before administering these drugs. The drugs do not cure the infection, but they may lower the patient's risk of severe liver damage by slowing or preventing HBV from reproducing further.

Drugs approved for treating chronic hepatitis B in children include alpha interferon (Intron A) and lamivudine (Zeffix or Epivir-HBV).

As of 2014, a trial in Hong Kong was under way on a new drug to treat chronic HBV infection. The drug, called ARC-520, is an RNA interference (RNAi) therapeutic. RNAi therapeutics obstruct replication, and in this case, ARB-250 is designed to stop hepatitis B progression by reducing the expression and release of new viral particles and proteins.

Liver transplant

If the patient develops fulminant hepatitis B or the liver is otherwise severely damaged by HBV, the only option is often a liver transplant. This is a serious operation with a lengthy recovery period; its success also depends on finding a suitable donor liver.

Alternatives

No alternative or complementary therapies are definitely known to be useful in treating or preventing hepatitis B. One herbal remedy often recommended by alternative practitioners is milk thistle (*Silybum marianum*). The seeds of the plant are used to make capsules, extracts, and herbal teas that are purported to be beneficial to liver function and a treatment option for cirrhosis and viral hepatitis. As of 2014, milk thistle has not been proven effective. While milk thistle is not known to be harmful, patients who wish to try this herb should consult their doctor first.

Prognosis

Each year an estimated 100,000 persons in the United States get hepatitis B. About 90% of all those infected will have acute disease only. They usually recover: The symptoms go away in 2–3 weeks, and the liver itself returns to normal in about four months. It is the remaining 10% with chronic infection who account for most serious complications and deaths from HBV infection. The course of chronic HBV infection in any particular patient is unpredictable. Some patients who do well at first may later develop serious complications. Chronic hepatitis leads to an increased risk of cirrhosis and liver cancer, and eventual death in about 1% of cases. Even when no symptoms of liver disease develop, chronic carriers remain a threat to others by serving as a source of infection.

KEY TERMS

Antibody—A substance formed in the body in response to a foreign body, such as a virus, which can then attack and destroy the invading virus.

Antigen—Part of an invading microorganism, such as a virus, that causes tissue damage (in hepatitis, to the liver), and that also stimulates the body's immune system to produce antibodies.

Carrier—A person who is infected with a virus or other disease organism but does not develop the symptoms of the disease.

Chronic—Long-term or recurrent.

Cirrhosis—Disruption of normal liver function by the formation of scar tissue and nodules in the liver.

Fulminant—Referring to a disease that comes on suddenly with great severity.

Hepatitis—A general term for inflammation of the liver. It can be caused by toxic substances or alcohol as well as infections.

Jaundice—A yellowish discoloration of the skin and whites of the eyes caused by increased levels of bile pigments from the liver in the patient's blood.

Pathogen—Any biological agent that causes illness or disease in its host. A pathogen may be a virus, bacterium, fungus, or prion.

Vaccine—A substance prepared from a weakened or killed virus that, when injected, helps the body to form antibodies that will attack an invading virus and may prevent infection altogether.

Prevention

Administration of a vaccine can prevent hepatitis B. An adult patient is given the first two doses of the vaccine a month apart and the third dose six months later. The vaccine is recommended for all persons under the age of 20, and can be given to newborns and infants as part of their regular vaccination series. Children usually receive the first vaccine between birth and two months of age, the second shot at one to four months, and the third at six to 18 months. The vaccine

is generally required for all children born on or after January 1, 1992, before they enter school.

People who should be vaccinated include healthcare workers, military personnel, firefighters and police, as well as people who travel frequently to countries with high rates of hepatitis B; who have hemophilia; who are undergoing treatment for kidney disease; and who inject illegal drugs. In addition, men who have sex with other men should be vaccinated. Immunity conferred by the vaccine lasts for at least 20 years among healthy individuals who started the vaccine regimen after they were six months of age.

Other preventive measures include:

- Practicing safe sex.
- Not sharing needles, razors, toothbrushes, or any other personal item that might have blood on it.
- Avoiding getting a tattoo or body piercing, as some people who perform these procedures do not sterilize their needles and other equipment properly.
- Getting tested for HBV infection if pregnant, as the virus can be transmitted from a mother to her unborn baby.
- Consulting a doctor before taking an extended trip to any country with high rates of hepatitis B.
- Carefully disinfecting any blood-stained surface or material with a mixture of chlorine bleach and water.

Hepatitis C

Definition

Hepatitis C infection is an inflammatory disease of the liver caused by the hepatitis C virus (HCV). The virus is most commonly transmitted from person to person through contaminated blood.

Description

Hepatitis C is an infection that often goes undetected until it has done significant damage to an individual's liver. The infection is divided into two phases, an acute phase (the first six months) and a chronic phase (after the first six months). A minority of individuals clear the virus from their bodies without treatment during the acute phase, but 60–85% will have a chronic HCV infection. Doctors do not yet know why some individuals clear the virus and others do not.

People may have no symptoms of illness at all during the acute phase of HCV infection and possibly only a mild flu-like syndrome later. Such symptoms of severe liver damage as nausea, **vomiting**, collection of fluid in the abdomen, and mental changes or severe psychiatric disturbances may not develop for 10–20 years after the initial infection with the virus.

Risk factors

People who are at increased risk of hepatitis C include:

- Those who abuse intravenous drugs (60% of new cases)
- People who use any form of cocaine, including non-injected (smoked or snorted) cocaine
- People who have unprotected sex with a large number of partners
- People who require hemodialysis for kidney disorders
- People who need frequent blood transfusions
- People who received clotting factor concentrates made before 1987
- Children born to mothers with hepatitis C
- People who are HIV-positive (about 25% of HIV-positive individuals in North America are also infected with hepatitis C)
- Health care workers who may get needlestick injuries

Demographics

Hepatitis C is the major source of chronic liver infection. As of 2014, about 4 million people in the United States were infected with HCV, and of those, 3.2 million have the chronic form of the disease. Approximately 20,000–30,000 new infections and 8,000–10,000 deaths from hepatitis C occur each year in the United States. The disease accounts for about 15% of cases of acute viral hepatitis, 60–70% of cases of chronic hepatitis, and up to 50% of cases of **cirrhosis**, end-stage **liver disease**, and **liver cancer**. HCV infection presently accounts for 40% of referrals to American liver clinics. The cost of treating hepatitis C in the United States is estimated to be more than $600 million a year.

Hepatitis C is more common among Hispanics and African Americans than among Caucasians, Asian Americans, or Native Americans. In terms of age groups, 65% of individuals with HCV infection are between the ages of 30 and 49 years. According to the Centers for Disease Control and Prevention (CDC), the rates of hepatitis C infection are highest among people born between 1945 and 1965. Most of these persons were likely infected during the 1970s and 1980s, when the rate of hepatitis C in North America was at its peak.

The World Health Organization (WHO) estimates that in 2014, about 180 million individuals worldwide are infected with the hepatitis C virus. The rates vary considerably from country to country, however, from 0.02% of the population in the United Kingdom to 6.5% in Africa to 22% in Egypt.

Causes and symptoms

Causes

Hepatitis C is caused by the HCV virus, which is a spherical, single-stranded RNA virus belonging to the family Flaviviridae. HCV is most often transmitted from one person to another through infected blood or blood products (as in shared needles), but it can also be transmitted from mother to child during **childbirth** or through sexual intercourse. Before 1992, the virus was sometimes transmitted through blood transfusions, hemodialysis, or transplanted organs from infected donors, but these are now rare events. In 1992, researchers invented a new test to check blood

KEY TERMS

Antibody—A substance made by the body in response to a foreign body, such as a virus, which is able to attack and destroy the invading virus.

Ascites—Accumulation of fluid in the abdomen.

Chronic—Recurrent or long-term. Chronic hepatitis C refers to an infection that has lasted longer than 6 months and has not been cleared by the individual's body.

Cirrhosis—Disruption of normal liver function by the formation of scar tissue and nodules in the liver. It is most commonly caused by alcoholism or hepatitis C.

Contamination—The process by which an object or body part becomes exposed to an infectious agent such as a virus.

Genotype—The genetic makeup of a cell or organism. There are six genotypes of the virus that causes hepatitis C.

Hepatitis—Inflammation of the liver. It can be caused by toxic substances or alcohol as well as infections.

Jaundice—A yellowish discoloration of the skin and whites of the eyes caused by increased levels of bile pigments from the liver in the individual's blood.

products for HCV. As a result, new infections per year in the United States declined from 240,000 in the 1980s to about 20,000–30,000 per year in 2014. The most common cause of HCV transmission at present is intravenous drug use; transfusion-related cases of hepatitis C now occur only once in every 2 million transfused units of blood.

Hepatitis C infection is sometimes divided into an early phase called the acute stage and a later phase called the chronic stage. The acute stage begins when the virus enters the body; it lasts for about six months. Antibodies to the virus can usually be detected 3–12 weeks after infection.

Symptoms

Eighty percent of individuals infected by the hepatitis C virus in its early stage do not have any symptoms or have only mild and nonspecific symptoms such as **fatigue**. In individuals who do develop symptoms, the average time from exposure to symptom onset is 4–12 weeks, although some people feel sick in as little as two weeks after exposure. Others have a flu-like syndrome marked by poor appetite or nausea, soreness in the area of the abdomen over the liver, or pains in the joints and muscles. Some may notice that their urine is darker than normal and looks like tea or cola.

If chronic HCV infection leads to liver disease 10–20 years later, the individual may have the following symptoms:

- severe loss of appetite
- nausea and vomiting, with blood in the vomit
- low-grade fever
- itchy skin
- jaundice (a yellowish discoloration of the whites of the eyes and the skin caused by an increase in the amount of bile pigments from the liver in the individual's blood)
- sleep disturbances
- swelling of the abdomen caused by fluid retention
- diarrhea
- clay-colored stools
- difficulty urinating
- confusion, hallucinations, difficulty concentrating, or other mental disturbances

Diagnosis

The diagnosis of hepatitis C infection is often delayed for years because many individuals with chronic HCV infection do not have noticeable or troublesome symptoms until damage to the liver has already occurred. In some cases, chronic hepatitis C is detected through routine blood testing for abnormal liver function or because the individual has a history of intravenous drug abuse, organ transplantation, hemodialysis treatment, or HIV infection. The diagnosis is based on the results of blood tests. The blood tests detect antibodies the body makes in response to HCV infection.

Examination

Many individuals infected with hepatitis C will not have any visible symptoms during a routine office examination. In some cases, however, the doctor may observe swelling or tenderness in the right upper quadrant of the individual's abdomen, enlargement of the spleen, signs of **jaundice**, scratches or abrasions on the skin, swollen ankles, and evidence of muscle wasting.

WWW.BOOKBAZ.IR

The doctor may also be able to detect the presence of fluid in the individual's abdomen (**ascites**).

Tests

Testing for chronic HCV infection begins with blood tests that indicate the presence of antibodies to the hepatitis C virus. Since antibody tests cannot tell whether the person is currently infected, a second blood test that looks for the virus's characteristic RNA is performed.

If the results are positive for both tests, the doctor will order a third blood test that determines the virus's specific genotype or genetic makeup. There are six known genotypes of the HCV virus as of 2014, and more than 50 subtypes have been identified. Knowing which type is involved helps to guide the individual's treatment. The most common HCV genotype in individuals in North America is genotype 1, found in 75% of individuals diagnosed with chronic hepatitis C.

Genotypes 1 and 2 are found worldwide whereas the others are limited to specific geographical regions. Genotype 3 is found in Australia, India, and Thailand. Genotype 4 is the most common HCV genotype in Egypt and the Middle East. Genotype 5 is found in South Africa, while genotype 6 is more common in Southeast Asia, particularly in Hong Kong, Macao, and Vietnam.

Other tests that are performed to guide treatment and monitor the effects of the drugs used to treat hepatitis C include a **complete blood count** (CBC), **liver function tests**, screening for co-infection with HIV or **hepatitis A** or B, and screening for alcohol and drug abuse.

Procedures

To determine the extent of damage to the individual's liver, the doctor may order a **liver biopsy**. In this procedure, a needle is inserted into the liver through the abdomen in order to remove a small sample of tissue for analysis.

The doctor may also order an **ultrasound** of the liver. Other imaging studies are not particularly useful in diagnosing hepatitis C.

Treatment

The goals of treatment for hepatitis C are 1) to achieve persistent absence of HCV RNA in the individual's blood six months and longer after the end of drug therapy; and 2) prevent the disease from progressing to cirrhosis or liver cancer.

Drugs

New drugs have improved the prognosis for people with chronic hepatitis C. These drugs reduce or eliminate HCV virus from the blood. They slow liver damage and reduce the risk of developing liver cancer, cirrhosis, or needing a liver transplant. Individuals with chronic hepatitis C should discuss with their doctor when to begin treatment, how to monitor the effectiveness of treatment, and how to handle sometimes serious side effects of these drugs. As of mid-2014, there are two treatment regimens approved by the U.S. Food and Drug Administration (FDA). Both treatments last 6–12 months and to be effective, the drugs must be taken exactly as prescribed.

A dual treatment uses two drugs and is approved for treating all six genotypes of the HCV virus. This therapy regimen is made up of an interferon plus ribavirin. Interferons are drugs that help the body's immune system fight the virus and protect healthy liver cells. The two interferons in use as of mid-2014 are Peginterferon alpha-2a (Pegasys) or Peginterferon alpha-2b (PegIntron). These are given once a week as an injection. Along with the interferon, the patient takes ribavirin (Copegus, Rebetol, Ribasphere). Ribavirin is a pill that fights viruses, but if taken without the interferon it does not work against HCV.

Forty to 50% of patients with genotype 1 HCV who complete dual therapy as directed clear the virus from their blood. People with genotype 2 or 3 who use dual therapy as directed clear the virus from their blood 60–80% of the time. As of 2014, not enough is known about the effect of dual therapy on genotypes 4, 5, or 6 to make predictions about its success rate.

A triple therapy regimen consisting of three drugs is approved by the FDA only to treat individuals with genotype 1 of HCV. This therapy regimen consists of an interferon, ribavirin, and either the drug boceprevir (Victrelis) or telaprevir (Incivik). Both these additional drugs are **antiviral drugs** that prevent the virus from reproducing. They are given as pills. Patients with genotype 1 who complete the triple therapy regimen as directed clear the virus from their blood 60–75% of the time.

Surgery

As of 2014, the only treatment for individuals who do not respond to treatment or who have severe liver disease is **liver transplantation**. A limiting factor is that there are many more individuals waiting for donated livers than there are suitable organs available. In addition, liver transplantation does not cure HCV infection. People who receive transplanted livers may

develop a recurrence of the virus. About 30% of recipients die, develop cirrhosis, or have the transplanted liver fail within five years of surgery, with the rate of failure increasing with each year of follow-up. The effectiveness of medication treatment of hepatitis C following a liver transplant is unclear as of 2014.

Individuals with chronic hepatitis C should stop drinking alcohol, as even small amounts can speed up the rate of liver damage. They should also be vaccinated against hepatitis A and **hepatitis B**, as these diseases also damage the liver.

Prognosis

The prognosis of hepatitis C has improved and new drugs are under development, but not everyone is able to accept the side effects of drug therapy or comply with the long period of treatment. In addition, drug therapy removes the virus from the blood in only half to three-quarters of individuals.

Women with chronic hepatitis C have better outcomes than men, and individuals infected at younger ages have better outcomes than those infected in middle age. The reason for these differences is not clear. Drug therapy is inappropriate for pregnant women, as ribavirin causes **birth defects** in the developing fetus.

A small percentage of individuals with hepatitis C develop medical conditions that are not related to the liver. It is thought that these conditions result from the body's immune response to the HCV virus. These conditions include **diabetes mellitus**, skin **rashes**, inflammation of the kidney (**glomerulonephritis**), non-Hodgkin lymphoma, and essential mixed cryoglobulinemia, a condition marked by the presence of abnormal proteins in the blood.

Prevention

A vaccine to prevent hepatitis C went into early clinical trial in 2012, but it is unlikely to be available for many years, even if it proves to be safe and effective. There is also no treatment that can prevent someone who recovered from one genotype of the virus from contracting a different genotype. Prevention depends on careful observation of good health practices in hospitals and clinics, and on individual lifestyle changes. The CDC recommends the following ways that individuals can lower their risk of getting hepatitis C:

- Do not use intravenous drugs. People who cannot quit should never share their needles, syringes, water, or other materials used to inject drugs. They should also get vaccinated against hepatitis A and hepatitis B.
- Do not share personal items (razors, toothbrushes, nail clippers, etc.) that might have blood on them.
- Avoid getting tattoos or body piercings. People who do get a tattoo, should at least make sure that the operator who performs the tattoo is using proper sterile procedure.
- Use latex condoms when having sex. Although it is rare for hepatitis C to be transmitted through sexual intercourse, it can happen.
- People who discover that they are infected with hepatitis C should not donate blood, organs, or tissues.
- Health care personnel must take special precautions when performing or assisting with surgical or dental procedures on individuals with hepatitis C.

Hepatitis D

Definition

Hepatitis D (or delta, the Greek letter "D"), is a form of liver inflammation that occurs only in patients who also are infected by the **hepatitis B** virus. Infection by the hepatitis delta virus (HDV) either occurs at the same time as hepatitis B develops or develops later when infection by hepatitis B virus (HBV) has entered the chronic (long-lasting) stage.

Description

Delta hepatitis can be quite severe, but it is seen only in patients already infected by HBV. In the late 1970s, Italian physicians discovered that some patients with hepatitis B had another type of infectious agent in their liver cells. Later the new virus—HDV—was confirmed by experimentally infecting chimpanzees. When both viruses are present, acute infection tends to be more severe. Furthermore, patients with both infections are more likely than those with HBV alone to develop chronic **liver disease**, and, when it occurs, it is more severe.

About 300 million persons worldwide carry HBV. Of them, at least 5% probably also have delta hepatitis. In North America HDV infection appears to be less frequent: 4% of all patients with acute hepatitis B have HDV infection. The delta virus causes an estimated 2% of all cases of acute viral hepatitis in the United States. The rate of HDV infection varies widely in different parts of the world; it is a very serious infection in some countries and quite mild in others. Chronic delta hepatitis is a more serious disease than either chronic hepatitis B alone or **hepatitis C**.

Certain individuals—the same ones who are at increased risk of developing hepatitis B—are the prime candidates to be infected by HDV. For example:

- Not infrequently, HDV infection occurs in patients with chronic HBV infection who also have hemophilia, a bleeding disease. These patients are at risk because they require large amounts of transfused blood and blood products that may contain HDV.
- In some areas, one-fourth to one-half of patients with chronic HBV infection who inject themselves with illicit drugs become infected by HDV as well. Drug abusers who share contaminated needles are likely to infect one another.
- Patients who get HBV infection by sexual contact may also be infected by HDV, although the delta virus is less often spread in this way than is HBV itself. Between 10–25% of homosexual men with chronic HBV infection harbor the delta virus.
- Like hepatitis B, HDV infection may develop in healthcare workers who are stuck with an infected needle, and it also can be spread within households when personal items such as a razor or toothbrush are shared.

Causes and symptoms

The delta virus is a small and incomplete viral particle. Perhaps this is why it cannot cause infection on its own. Its companion virus, HBV, actually forms a covering over the HDV particle. In chronically ill patients (those whose virus persists longer than six months), the combined viruses cause inflammation throughout the liver and eventually destroy the liver cells, which are then replaced by scar tissue. This scarring is called **cirrhosis**.

When HBV and HDV infections develop at the same time, a condition called coinfection, recovery is the rule. Only 2–5% of patients become chronic carriers (have the virus remain in their blood more than six months after infection). It may be that HDV actually keeps HBV from reproducing as rapidly as it would if it were alone, so chronic infection is less likely.

When HBV infection occurs first and is followed by HDV infection, the condition is called superinfection. This is a more serious situation. Between half and two-thirds of patients with superinfection develop severe acute hepatitis. Once the liver cells contain large numbers of HBV viruses, HDV tends to reproduce more actively. Massive infection and liver failure are more common in superinfection. The risk of **liver cancer**, however, is no greater than from hepatitis B alone.

As with other forms of hepatitis, the earliest symptoms are nausea, loss of appetite, joint pains, and tiredness. There may be **fever** (not marked), and an enlarged liver may cause discomfort or actual **pain** in the right upper part of the abdomen. Later, **jaundice** (a yellowing of the skin and whites of the eyes that occurs when the liver is no longer able to eliminate certain pigmented substances) may develop.

Diagnosis

HDV infection may be diagnosed by detecting the antibody against the virus. This test cannot detect acute coinfection or superinfection as early as when symptoms first develop. Antibody against HDV usually is found no sooner than 30 days after symptoms appear. Until recently, the virus itself could only be identified by testing a small sample of liver tissue.

KEY TERMS

Alpha-interferon—A natural body substance that can be made in large quantities and is an effective treatment for some types of viral inflammatory disease, including hepatitis C.

Antibody—A substance formed in the body in response to an invading microorganism, such as a virus, which can attack and destroy the invading virus.

Coinfection—Invasion of the body by two viruses at about the same time.

Hemophilia—A bleeding disease that may call for the transfusion of large amounts of blood and blood products.

Superinfection—Infection by a second virus after a previous infection by a different virus has become well established.

Scientists are developing a blood test for HDV that should make diagnosis faster and easier. When HDV is present, liver enzymes (proteins made by the liver) are present in abnormally high amounts. In some patients with coinfection, the enzyme levels peak twice, once when HBV infection starts and again at the time of HDV infection.

Treatment

As in any form of hepatitis, patients in the acute stage should rest in bed as needed, eat a balanced diet, and avoid alcohol. Alpha-interferon, the natural body substance that helps control hepatitis C, has generally not been found helpful in treating hepatitis D. If the liver is largely destroyed and has stopped functioning, **liver transplantation** is an option. Even when the procedure is successful, the disease often recurs and cirrhosis may actually develop more rapidly than before.

Prognosis

A large majority of patients with coinfection of HBV and HDV recover from an episode of acute hepatitis. However, about two-thirds of patients chronically infected by HDV go on to develop cirrhosis of the liver. In one long-term study, just over half of patients who became carriers of HDV had moderate or severe liver disease, and one-fourth of them died. If very severe liver failure develops, the chance of a patient surviving is no better than 50%. A liver transplant may improve this figure to 70%. When transplantation is done for cirrhosis, rather than for liver failure, nearly 90% of patients live five years or longer. The major concern with transplantation is infection of the transplanted liver; this may occur in as many as 40% of transplant patients.

When a child with viral hepatitis develops cirrhosis, HDV infection is commonly responsible. A woman who develops delta hepatitis while pregnant will do as well as if she were not pregnant, and there is no increased risk that the newborn will be malformed in any way.

Prevention

The vaccine against hepatitis B also prevents delta hepatitis, since it cannot occur unless HBV infection is present. Hopefully, a vaccine can be developed that will keep delta infection from developing in chronic HBV carriers. If a person already has HBV infection, any exposure to blood should be strictly avoided. A high level of sexual activity with multiple partners is also a risk factor for delta hepatitis.

Hepatitis, drug-induced

Definition

Inflammation of the liver due to an adverse reaction with a drug is known as drug-induced hepatitis.

Description

The liver is a very important organ to the body. It is a large internal organ weighing more than 3 lb. (1.4 kg) in the average adult. It performs over 100 functions including formation of bile; **detoxification** of harmful substances; vitamin storage; and metabolism of carbohydrates, fats, and proteins. Serious complications could arise when the liver becomes inflamed due to

WWW.BOOKBAZ.IR

hepatitis when it is not able to perform these tasks. A virus most often causes hepatitis but certain drugs can also induce it.

Drug-induced hepatitis (also called toxic hepatitis) occurs in eight in every 10,000 people because the liver reacts abnormally during drug exposure, leading to liver damage. This pathology causes the liver not to function properly and the symptoms can begin to be seen. Women tend to be affected almost twice as often as men. Older people are more prone to this type of hepatitis because their bodies are not able to repair themselves as fast as younger people. Drugs associated with drug-induced hepatitis include **acetaminophen**, **vitamin A**, and PTU (a drug treatment for **tuberculosis**).

Causes and symptoms

There are three general types of drug-induced hepatitis: toxic, metabolic idiosyncrasy, and immunologic idiosyncrasy. With toxic hepatitis, liver damage as the result of a drug complication with hepatotoxins happens to everyone who takes that particular drug. On the other hand, hepatitis resulting from a metabolic or immunologic idiosyncrasy only happens to certain people, those predisposed to a particular idiosyncrasy.

In patients with a metabolic idiosyncrasy the person metabolizes the drug differently than most people causing a harmful by-product that damages the liver. A metabolic idiosyncrasy is seen in 0.1-2% of people and it is complicated by use of alcohol.

With an immunologic idiosyncrasy the patient's body recognizes the metabolized drug by-products as foreign. This leads to the destruction of liver cells containing the by-product via the immune system resulting in hepatitis. An immunologic idiosyncrasy is seen in less than one person per 10,000 (0.01%) people and is more than twice as common in women.

The symptoms of drug-induced hepatitis are similar to viral hepatitis. Drug induced hepatitis tends to be acute. If it is not caught soon enough the damage could be permanent resulting in chronic hepatitis. Some of the common symptoms are:

- nausea
- vomiting
- headache
- anorexia
- jaundice
- clay color stools
- dark urine
- hepatomegaly

KEY TERMS

Hepatitis—General inflammation of the liver.

Hepatomegaly—General swelling of the liver.

Hepatotoxin—A substance that is toxic to the liver.

Idiosyncrasy—A defect in that particular pathway resulting in an abnormality.

Diagnosis

Diagnosis is typically made through a physical exam along with a patient history to identify any possible hepatotoxins. Blood tests are usually done as well. An increased **white blood cell count** is typical.

Treatment

There is not any specific treatment other than immediate discontinuance of the causative agent. Rest during the acute phase of the disease is vital along with the intake of fluids to maintain hydration.

Prognosis

Usually, the symptoms will go away after the drug has been eliminated due to the liver repairing itself. A full recovery is typically expected unless it was not treated quickly resulting in more liver damage being done than normal.

Prevention

If there is a history of liver damage certain medications should not be taken. Doctors will be familiar with these.

Hepatitis E

Definition

The hepatitis E virus (HEV) is a common cause of hepatitis that is transmitted via the intestinal tract, and is not caused by the **hepatitis A** virus. Spread most

often by contaminated drinking water, HEV infection occurs mainly in developing countries.

Description

Hepatitis E is also known as epidemic non-A, non-B hepatitis. Like hepatitis A, it is an acute and short-lived illness that can sometimes cause liver failure. HEV, discovered in 1987, is spread by the fecal-oral route. It is constantly present (endemic) in countries where human waste is allowed to get into drinking water without first being purified. Large outbreaks (epidemics) have occurred in Asian and South American countries where there is poor sanitation. In the United States and Canada no outbreaks have been reported, but persons traveling to an endemic region may return with HEV.

Causes and symptoms

There are at least two strains of HEV, one found in Asia and another in Mexico. The virus may start dividing in the gastrointestinal tract, but it grows mostly in the liver. After an incubation period (the time from when a person is first infected by a virus until the appearance of the earliest symptoms) of two to eight weeks, infected persons develop a **fever**, may feel nauseous, lose their appetite, and often have discomfort or actual **pain** in the right upper part of the abdomen where the liver is located. Some develop yellowing of the skin and the whites of the eyes (**jaundice**). Most often the illness is mild and disappears within a few weeks with no lasting effects. Children younger than 14 years and persons over age 50 seldom have jaundice or show other clinical signs of hepatitis.

Hepatitis E never becomes a chronic (long-lasting) illness, but on rare occasions the acute illness damages and destroys so many liver cells that the liver can no longer function. This is called fulminant liver failure and may cause death. Pregnant women are at much higher risk of dying from fulminant liver failure; this increased risk is not true of any other type of viral hepatitis. The great majority of patients who recover from acute infection do not continue to carry HEV and cannot pass on the infection to others.

Diagnosis

HEV can be found by microscopically examining a stool sample, but this is not a reliable test, as the virus often dies when stored for a short time. Like other hepatitis viruses, HEV stimulates the body's immune system to produce a substance called an antibody, which can swallow up and destroy the virus. Blood tests can determine elevated antibody levels, which indicate the presence of HEV virus in the body. These antibody blood tests are not widely available.

KEY TERMS

Antibody—A substance made by the body's immune system in response to an invading virus, the antibodies then attack and destroy the virus.

Incubation period—The time from when a person is first infected by a virus until the appearance of the earliest symptoms.

Jaundice—Yellowing of the skin that occurs when pigments normally eliminated by the liver collect in high amounts in the blood.

Sanitation—The process of keeping drinking water, foods, or any anything else with which people come into contact free of microorganisms such as viruses.

Vaccine—A substance prepared from a weakened or killed virus that, when injected, stimulates the immune system to produce antibodies that can prevent infection by the natural virus.

Treatment

There is no way of effectively treating the symptoms of any acute hepatitis, including hepatitis E. During acute infection, a patient should eat a balanced diet and rest in bed as needed.

Prognosis

In the United States, hepatitis E is not a fatal illness, but elsewhere about 1–2% of those infected die of advanced liver failure. In pregnant women the death rate is as high as 20%. It is not clear whether having hepatitis E once guarantees against future HEV infection.

Prevention

Most attempts to use blood serum containing HEV antibody to prevent hepatitis in those exposed to HEV have failed. If this approach could be made to work, that pregnant women living in endemic areas could be protected. No vaccine is available, though several are being tested. It also is possible that effective anti-viral drugs will be found. The best ways to prevent hepatitis E are to provide safe drinking water and take precautions to use sterilized water and beverages when traveling.

Hepatitis virus studies *see* **Hepatitis virus tests**

Hepatitis virus tests

Definition

Viral hepatitis is any type of liver inflammation caused by a viral infection. The three most common viruses now recognized to cause **liver disease** are **hepatitis A**, **hepatitis B**, and **hepatitis C**. Several other types have been recognized: **hepatitis D**, **hepatitis E**, and the recently identified hepatitis G. A seventh type (hepatitis F) is suspected but not yet confirmed.

Purpose

The different types of viral hepatitis produce similar symptoms, but they differ in terms of transmission, course of treatment, prognosis, and carrier status. When the clinical history of a patient is insufficient for differentiation, hepatitis virus tests are used as an aid in diagnosis and in monitoring the course of the disease. These tests are based primarily on antigen-antibody reactions. Antigens are proteins foreign to the body, and antibodies are another type of protein manufactured by lymphocytes (a type of white blood cell) to neutralize the antigen.

Description

There are five major types of viral hepatitis.

Hepatitis A

Commonly called infectious hepatitis, the hepatitis A virus (HAV) is considered a mild disease, most often spread by food and water contamination or sometimes through sexual contact. Immunologic tests are not commercially available for the HAV antigen, but two types of antibodies to HAV can be detected. IgM antibody (anti-HAV/IgM) appears approximately three to four weeks after exposure and returns to normal within several months. IgM anti-HAV is the preferred method of detection. IgG (anti-HAV/IgG) appears approximately two weeks after the IgM begins to increase and remains positive. Acute hepatitis is suspected if IgM is elevated; conversely, if IgG is elevated without IgM, a convalescent stage of HAV is presumed. IgG antibody can remain detectable for decades after infection.

Hepatitis B

Commonly known as serum hepatitis, hepatitis B virus (HBV) can be mild or severe, as well as acute (of limited duration) or chronic (ongoing). It is usually spread by sexual contact with another infected person, through contact with infected blood, by intravenous drug use, or from mother to child at birth.

HBV, also called the Dane particle, is composed of an inner protein core surrounded by an outer protein capsule. The outer capsule contains the hepatitis B surface antigen (HBsAg), formerly called the Australia antigen. The inner core contains HBV core antigen (HBcAg) and the hepatitis B e-antigen (HBeAg). Antibodies to these antigens are called anti-HBs, anti-HBc, and anti-HBe. Testing for these antigens and antibodies includes:

- Hepatitis B surface antigen (HBsAg). This is the first test for hepatitis B to yield abnormal results. HBsAg begins to elevate before the onset of clinical symptoms, peaks during the first week of symptoms, and usually disappears by the time the accompanying jaundice (yellowing of the skin and other tissues) begins to subside. HBsAg indicates an active HBV infection. A person is considered to be a carrier if this antigen persists in the blood for six or more months. It can be detected by radioimmunoassay (RIA) or by enzyme immunoassay (EIA) and is the primary bloodborne indicator of HBV infection.
- Hepatitis B surface antibody (anti-HBs). This appears approximately one month after the disappearance of the HBsAg, signaling the end of the acute infection period. Anti-HBs is the antibody that demonstrates immunity after administration of the hepatitis B vaccine. Its presence also indicates immunity to subsequent infection.
- Hepatitis B core antigen (HBcAg). No tests are commercially available to detect this antigen, and it is not detectable in blood serum.
- Hepatitis B core antibody (anti-HBc). This appears just before acute hepatitis develops and remains elevated (although it slowly declines) for years. It is also present in chronic hepatitis. The hepatitis B core antibody is elevated during the time lag between the disappearance of the hepatitis B surface antigen and the appearance of the hepatitis B surface antibody in

an interval called the window. During this time, the hepatitis B core antibody is the only detectable marker of a recent hepatitis B infection.

- Hepatitis B e-antigen (HBeAg). This is more useful as an index of infection than for diagnostic purposes. The presence of this antigen correlates with early and active disease, as well as with high infectivity in patients with acute HBV infection. When HBeAg levels persist in the blood, the development of chronic HBV infection is suspected.
- Hepatitis B e-antibody (anti-HBe). In the bloodstream, this indicates a reduced risk of infectivity in patients who have previously been HBeAg positive. Chronic hepatitis B surface antigen carriers can be positive for either HBeAg or anti-HBe, but are less infectious when anti-HBe is present. Antibody to the e-antigen can persist for years, but usually disappears earlier than anti-HBs or anti-HBc.

Hepatitis C

Previously known as non-A non-B hepatitis, this disease is primarily caused by the hepatitis C virus (HCV). It is generally mild, but it is more likely than hepatitis B to lead to chronic liver disease, possible liver failure, and the eventual need for transplant. Chronic carrier states develop in more than 80% of patients, and chronic liver disease is a major problem. As many as 20% of patients with chronic hepatitis C will develop liver failure or **liver cancer**. HCV is spread through sexual contact as well as through sharing drug needles, although nearly half of infections cannot be traced to their origin.

Hepatitis C is detected by HCV serology (tests on blood sera). A specific type of assay called enzyme-linked immunosorbent assay (ELISA) was developed to detect antibody to hepatitis C for diagnostic purposes, as well as for screening blood donors. Most cases of post-transfusion non-A, non-B hepatitis are caused by HCV, but application of this test has virtually eliminated post-transfusion hepatitis. An HCV viral titer to detect HCV RNA in the blood is available, and IgM anti-HCV core is proving to be a useful acute marker of HCV infection.

Hepatitis D

Also called delta hepatitis, hepatitis D virus (HDV) occurs only in those who have HBV in the blood from a past or simultaneously occurring infection. Experts believe transmission may occur through sexual contact, but further research is needed to confirm. Most cases occur among those who are frequently exposed to blood and blood products. Many cases also occur among drug users who share contaminated needles. Hepatitis D virus (HDV) antigen can be detected by radioimmunoassay within a few days after infection, together with IgM and total antibodies to HDV.

Hepatitis E

Caused by the hepatitis E virus (HEV), this disease is actually another type of non-A non-B hepatitis. The virus is most often spread through fecally contaminated water, but the role of person-to-person transmission is unclear. This form of hepatitis is quite rare in the United States, although it may be present in the blood of up to 21% of the U.S. population, without clinical symptoms. There are currently no antigen or antibody tests widely available to accurately detect HEV.

Preparation

Hepatitis virus tests require a blood sample, although HEV can be detected in stool. It is not necessary for the patient to withhold food or fluids before any of these tests unless requested to do so by the physician.

Risks

Risks for these tests are minimal for the patient, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Normal reference ranges for the antigen/antibody tests are as follows:

- hepatitis A antibody, IgM: Negative
- hepatitis B core antibody: Negative
- hepatitis B e antibody: Negative
- hepatitis B e-antigen: Negative
- hepatitis B surface antibody: Varies with clinical circumstance (The presence of anti-HBs indicates past infection with resolution of previous hepatitis B infection, or vaccination against hepatitis B; additional patient history may be necessary for diagnosis.)
- hepatitis B surface antigen: Negative
- hepatitis C serology: Negative
- hepatitis D serology: Negative

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A protein that the body produces in response to a foreign invader, such as a virus, bacteria, fungus, or allergen. The production of each antibody is triggered by a specific antigen.

Antigen—A substance, usually a protein, that is capable of provoking an immune response.

Hepatitis—Disease characterized by inflammation of the liver.

Serology—The analysis of the contents and properties of blood serum.

Serum—The clear pale yellow liquid that separates from a clot when blood coagulates.

Virus—A tiny disease-causing agent that can reproduce only in living cells and cause a variety of infectious diseases.

Abnormal results

Hepatitis A: A single positive anti-HAV test may indicate previous exposure to the virus, but due to the antibody persisting so long in the bloodstream, only evidence of a rising anti-HAV titer confirms hepatitis A. Determining recent infection rests on identifying the antibody as IgM (associated with recent infection). A negative anti-HAV test rules out hepatitis A.

Hepatitis B: High levels of HBsAg that continue for three or more months after onset of acute infection suggest development of chronic hepatitis or carrier status. Detection of anti-HBs signals late convalescence or recovery from infection. This antibody remains in the blood to provide immunity to reinfection.

Hepatitis C: Anti-HBc develops after exposure to hepatitis B. As an early indicator of acute infection, antibody (IgM) to core antigen (anti-HBc IgM) is rarely detected in chronic infection, so it is useful in distinguishing acute from chronic infection, and hepatitis B from non-A, non-B.

Herbalism, traditional Chinese

Definition

Chinese herbalism is one of the major components of **traditional Chinese medicine** (TCM), or Oriental medicine (OM). In TCM, herbs are often used in conjunction with other techniques, such as **acupuncture** or massage. Chinese herbalism is a holistic medical system, meaning that it looks at treating a patient as a whole person, looking at the mental and spiritual health, as well as the physical health, of the individual. Illness is seen as a disharmony or imbalance among these aspects of the individual. Chinese herbalism has been practiced for over 4,000 years.

One of the earliest and certainly the most important Chinese herbal text is the *Huang Ti Nei Ching*, or *Yellow Emperor's Classic of Internal Medicine*. It is believed to be authored by Huang Ti during his reign over China, which started about 2697 B.C. Since that time, herbal practices have been more extensively documented and refined. In modern China, traditional Chinese herbalism is taught alongside conventional Western pharmacology. Chinese herbal remedies have been used in the West only relatively recently, over the past two decades. These remedies are more gentle and natural than conventional medicines. In addition, they have fewer unpleasant side effects. Individuals with chronic disorders in particular are increasingly drawn to the holistic aspect of Chinese herbalism and TCM in general.

Purpose

Because it is a safe, inexpensive solution to health problems of all kinds, Chinese herbalism is very popular in China. In recent years, herbalism has been modernized with the introduction of quality control. For example, herbs are subjected to absorption spectrometry to determine levels of heavy metals found in some. Because they are standardized, Chinese herbs are safer for self-treatment. This puts the individual, not the physician, in charge of the individual's health; that is a basic goal of Chinese herbalism.

Chinese herbalism offers unique advice regarding what foods can help and what can hinder, and an herbalist can help an individual discover foods that might cause an allergic reaction. In addition, Chinese herbs stimulate the immune system and provide beneficial nutrients, aside from their role in curing illness.

At M.D. Anderson Hospital in Texas, medical research has confirmed that patients undergoing **chemotherapy** showed an improved degree of immune function when they took the tonic herb astragulus (*huang qi*). (It is well known that chemotherapy suppresses the immune system.) Research also showed that T-cell and macrophage activity and interferon production was increased in patients using the Chinese herbs ganoderma, lentinus, and polyporous, helping the body fight cancer cells. Agents also found in ganoderma were found to inhibit platelet aggregation and thrombocyte formation, which would be helpful to counter circulation and heart problems.

An ingredient of **ginseng** was found to promote adrenal function, which would give the herb properties of enhancing many hormone functions in the body.

Five popular Chinese herbs used in the United States

Herb	Purpose
Astragalus (huang qi)	Builds immune system; offsets side effects of chemotherapy and radiation treatments
Dong quai (dang gui)	Stimulates the production of red blood cells and bone marrow; increases cardiovascular endurance; regulates menstrual disorders
Ginseng (ren shen)	Increases physical stamina; general tonic
Reishi mushroom (ling zhi)	Eliminates toxins; increases physical stamina
Schisandra (wu wei zu)	Prevents fluid loss (e.g., excessive sweating, runny nose, incontinence)

(Table by PreMediaGlobal. © Cengage Learning®.)

Description

Origins

HISTORICAL BACKGROUND. Traditional Chinese medicine originated in the region of eastern Asia that today includes China, Tibet, Vietnam, Korea, and Japan. Tribal shamans and holy men who lived as hermits in the mountains of China as early as 3500 B.C. practiced what was called the "Way of Long Life." This regimen included a diet based on herbs and other plants; kung-fu exercises; and special breathing techniques that were thought to improve vitality and life expectancy.

After the Han dynasty, the next great age of Chinese medicine was under the Tang emperors, who ruled from A.D. 608 to 906. The first Tang emperor established China's first medical school in A.D. 629. Under the Song (A.D. 960–1279) and Ming (A.D. 1368–1644) dynasties, new medical schools were established, their curricula and qualifying examinations were standardized, and the traditional herbal prescriptions were

WWW.BOOKBAZ.IR

written down and collected in encyclopedias. One important difference between the development of medicine in China and in the West is the greater interest in the West in surgical procedures and techniques.

PHILOSOPHICAL BACKGROUND: THE COSMIC AND NATURAL ORDER. In Taoist thought, the Tao, or universal first principle, generated a duality of opposing principles that underlie all the patterns of nature. These principles, yin and yang, are mutually dependent as well as polar opposites. They are basic concepts in traditional Chinese medicine. Yin represents everything that is cold, moist, dim, passive, slow, heavy, and moving downward or inward; while yang represents heat, dryness, brightness, activity, rapidity, lightness, and upward or outward motion. Both forces are equally necessary in nature and in human well-being, and neither force can exist without the other. The dynamic interaction of these two principles is reflected in the cycles of the seasons, the human life cycle, and other natural phenomena. One objective of traditional Chinese medicine is to keep yin and yang in harmonious balance within a person.

In addition to yin and yang, Taoist teachers also believed that the Tao produced a third force, primordial energy or qi (also spelled chi or ki). The interplay between yin, yang, and qi gave rise to the Five Elements of water, metal, earth, wood, and fire. These entities are all reflected in the structure and functioning of the human body.

THE HUMAN BEING. Traditional Chinese physicians did not learn about the structures of the human body from dissection because they thought that cutting open a body insulted the person's ancestors. Instead they built up an understanding of the location and functions of the major organs over centuries of observation, and then correlated them with the principles of yin, yang, qi, and the Five Elements. Thus, wood is related to the liver (yin) and the gall bladder (yang); fire to the heart (yin) and the small intestine (yang); earth to the spleen (yin) and the stomach (yang); metal to the lungs (yin) and the large intestine (yang); and water to the kidneys (yin) and the bladder (yang). The Chinese also believed that the body contains Five Essential Substances, which include blood, spirit, vital essence (a principle of growth and development produced by the body from qi and blood), fluids (all body fluids other than blood, such as saliva, spinal fluid, sweat, etc.), and qi.

Chinese herbal treatment differs from **Western herbalism** in several respects. In Chinese practice, several different herbs may be used, according to each plant's effect on the individual's Qi and the Five Elements. There are many formulas used within traditional Chinese medicine to treat certain common imbalance patterns. These formulas can be modified to fit specific individuals more closely.

A traditional Chinese herbal formula typically contains four classes of ingredients, arranged in a hierarchical order: a chief (the principal ingredient, chosen for the patient's specific illness); a deputy (to reinforce the chief's action or treat a coexisting condition); an assistant (to counteract side effects of the first two ingredients); and an envoy (to harmonize all the other ingredients and convey them to the parts of the body that they are to treat).

Methods of diagnosis

A Chinese herbalist will not prescribe a particular herb on the strength of symptoms only, but will take into consideration the physical condition, emotional health, and mental state of the patient. He or she may look at the condition of the patient's hair, skin, and tongue, as well as the appearance of the eyes, lips, and general complexion. The practitioner then listens to the sounds the body makes when breathing. He or she may smell the breath, body odor, or sputum in diagnosis.

TCM practitioners take an extensive medical history of a patient. He or she may ask about dietary habits, lifestyle, and sleep patterns. The patient will be questioned about chief medical complaints, as well as on his or her particular emotional state and sexual practices.

Chinese herbalists employ touch as a diagnostic tool. They may palpate the body or use light massage to assess the patient's physical health. Another chief component of Chinese medical diagnosis is pulse diagnosis, or sphygmology. This is a very refined art that takes practitioners years to master. Some practitioners can detect 12 different pulse points that correspond to the 12 major organs in Chinese medicine. There are over 30 pulse qualities that practitioners are able to detect on each point. The strength, speed, quality, and rhythm of the pulse, to name a few, will be determined before a diagnosis is given.

Herbs

Chinese herbs may be used alone or in combination. Relatively few are used alone for medicinal purposes. Practitioners believe that illness can be effectively treated by combining herbs based on their various characteristics and the patient's overall health. Every herb has four basic healing properties: nature, taste, affinity, and effect.

An herb's nature is described according to its yin or yang characteristics. Yang, or warming, herbs treat cold deficiencies. They are frequently used in the treatment of the upper respiratory tract, skin, or extremities. Yin, or cooling, herbs, treat hot excess conditions. They are most often used to treat internal conditions and problems with organs. Herbs can also be neutral in nature.

An herb's taste does not refer to its flavor, but to its effect on qi, blood, fluids, and phlegm. Sour herbs have a concentrating action. They are prescribed to treat bodily excess conditions, such as **diarrhea**, and concentrate qi. Bitter herbs have an eliminating or moving downward action. They are used to treat coughs, **constipation**, and heart problems. Sweet or bland herbs have a harmonizing action. They are used as restorative herbs and to treat **pain**. Spicy herbs have a stimulating action. They are prescribed to improve blood and qi circulation. Salty herbs have a softening action. They are used to treat constipation and other digestion problems.

An herb's affinity describes its action on a specific bodily Organ. (Chinese medicine does not have the anatomical correlation for organ names. They correspond more closely to the organ's function.) Sour herbs have an affinity for the Liver and Gallbladder. Bitter herbs act on the Heart and Small Intestine. Sweet and bland herbs affect the Stomach and Spleen. Spicy herbs have an affinity for Lungs and Large Intestine, whereas salty herbs act on the Kidneys and Bladder.

Chinese herbs are lastly classified according to their specific actions, which are divided into four effects. Herbs that dispel are used to treat an accumulation, sluggishness, or spasm by relaxing or redistributing. Herbs with an astringent action are used to consolidate or restrain a condition characterized by discharge or excessive elimination. Herbs that purge treat an obstruction or "poison" by encouraging elimination and **detoxification**. Tonifying herbs nourish, support, and calm where there is a deficiency.

Treatment of diabetes

The incidence of diabetes has increased quite dramatically in recent years, especially in the United States, where in general people take less **exercise**, and food is taken in greater quantity with a general reduction in quality. This has lead to a scramble to find new solutions to the problem, and many researchers have focused their interest on Chinese herbal remedies. In the search for more effective and more convenient treatments, the alkaloid berberine has come under close scrutiny for its many uses, including the treatment of diabetes. In trials, rats given a mixture of berberine and alloxan showed less likelihood of incurring a rise in blood sugar. Patients with type II diabetes who were given 300–600 mg of berberine daily for between one and three months, showed a reduction in blood sugar levels, when taken in conjunction with a controlled diet.

Treatment of AIDS and cancer

Independent researchers are investigating indications that Chinese herbalism can reduce the toxicity of chemotherapy and other medications, in addition to stimulating immune responses.

Preparations

Those who are unfamiliar with Chinese herbs and their uses should consult a practitioner before starting any treatment. Once a remedy is prescribed, it may be found at Oriental markets or health food stores. The remedies used in Chinese herbalism are standardized and sold prepared for use, with instructions for dosage. A Chinese herbalist may prescribe herbs to be made into tea, or taken as capsules.

Precautions

When treating a patient, the herbalist will aim to gently "nudge" the system into shape, rather than producing any immediate reaction. A return to health, therefore, may take time, and it is important that the patient realizes the principle of the treatment. Some practitioners estimate that treatment will take a month for every year that a chronic condition has existed. The advantage of the slow pace is that if there is a bad reaction to any herb, which is rare, it will be mild because the treatment itself is gentle.

As with most naturopathic therapies, Chinese herbal remedies work best when taken in conjunction with a healthy lifestyle and program of exercise.

Side effects

Some Chinese herbs are incompatible with certain prescription drugs, certain foods, or should not be taken during **pregnancy**. To be certain, a Chinese herbalist should be consulted.

Research and general acceptance

At present, there is renewed interest in the West in traditional Chinese medicine and Chinese herbalism. Of the 700 herbal remedies used by traditional Chinese practitioners, over 100 have been tested and found effective by the standards of Western science. Several United States agencies, including the National Institutes of Health, the Office of Alternative Medicine,

Patricia Skinner

Herbalism, Western

Definition

Western herbalism is a form of the healing arts that draws from herbal traditions of Europe and the Americas and that emphasizes the study and use of European and Native American herbs in the treatment and prevention of illness. Western herbalism is based on physicians' and herbalists' clinical experience and traditional knowledge of medicinal plant remedies preserved by oral tradition and in written records over thousands of years. Western herbalism, like the much older system of **traditional Chinese medicine**, relies on the synergistic and curative properties of the plant to treat symptoms and disease and maintain health.

Western herbalism is based upon pharmocognosy, the study of natural products. Pharmocognosy includes the identification, extraction methods, and applications of specific plant constituents responsible for specific therapeutic actions, such as the use of **digoxin** from Digitalis leaf for **heart failure**. These constituents are extracted, purified and studied in vitro, in vivo, and in clinical research. They may be concentrated to deliver standardized, set doses. Sometimes, the natural constituent can be synthesized in the lab, or changed and patented. Practitioners may choose to use fresh medicinal plants, simple extracts, or standardized extracts.

In standardized extracts, a specific quantity of a constituent is called a marker compound, and it may or may not be the active constituent(s) in the plant medicine. There are preparations with standardized active constituent quantities and preparations with greater emphasis on quality of crude plant material and traditional preparation methodology than on finalized total quantity of marker compounds. The preference between the two for precision dosing is philosophical, practical and variable. When using plant extracts in which the active constituents and their cofactors are well established, or the therapeutic and lethal dose are close, standardized products are often preferred. When using plant extracts whose active constituents remain obscure, or the active constituents when purified produce weaker therapeutic results or more undesirable side effects, the products produced under good manufacturing processes and according to the traditional *National Formulary U. S. Dispensatory* or *U. S. Pharmacopeia* are preferred.

Purpose

The benefits of botanical medicine may be subtle or dramatic, depending on the remedy used and the symptom or problem being addressed. Herbal remedies usually have a much slower effect than pharmaceutical drugs. Some herbal remedies have a cumulative effect and work slowly over time to restore balance, and others are indicated for short-term treatment of acute

A selection of Western herbal medical equipment and traditional herbs, including foxglove (upper right), ginger (center right), and periwinkle (lower left). *(Photo Researchers, Inc.)*

symptoms. When compared to the pharmaceutical drugs, herbal remedies prepared from the whole plant have relatively few side effects. This is due to the complex chemistry and synergistic action of the full range of phytochemicals present in the whole plant and the relatively lower concentrations. They are generally safe when used in properly designated therapeutic dosages and less costly than the isolated chemicals or synthetic prescription drugs available from western pharmaceutical corporations.

Description

Origins

More than 2,500 years ago Hippocrates wrote, "In medicine one must pay attention not to plausible theorizing but to experience and reason together." This Greek physician and herbalist from the fourth century B.C. is considered the father of Western medicine. He stressed the importance of diet, water quality, climate, and social environment in the development of disease. Hippocrates believed in treating the whole person, rather than merely isolating and treating symptoms. He recognized the innate capacity of the body to heal itself, and emphasized the importance of keen observation in the medical practice. He recommended simple herbal remedies to assist the body in restoring health.

Ancient Greek medicine around the fifth century B.C. was a fertile ground for contrasting philosophies and religions. Greek physicians were influenced by the accumulated medical knowledge from Egypt, Persia, and Babylon. Medical advances flourished and practitioners and scholars were free to study and practice without religious and secular constraints. In the fourth century B.C., Theophrastus wrote the *Historia Plantarum*, considered to be the founding text in the science of botany.

During the first century A.D. Dioscorides, a Greek physician who traveled with the Roman legions, produced five medical texts. His herbal text, known as the *De Materia Medica* is considered to be among the most influential of all western herbal texts. It became a standard reference for practitioners for the next 1,500 years. This influential book also included information on medicinal herbs and treatments that had been used for centuries in Indian **Ayurvedic medicine**. Galen of Pergamon, who also lived in the first century A.D., was a Roman physician and student of anatomy and **physiology**. He authored a recipe book containing 130 antidotes and medicinal preparations. These elaborate mixtures, known as galenicals, sometimes included up to 100 herbs and other substances. This complex approach to herbal medicine was a dramatic change from the simple remedies recommended by Hippocrates and employed by traditional folk healers. Galen developed a rigid system of medicine in which the physician, with his specialized knowledge of complex medical formulas, was considered the ultimate authority in matters of health care. The Galenic system, relying on theory and scholarship rather than observation, persisted throughout the Middle Ages. The Galenical compounds, along with bloodletting and purging, were among the drastic techniques practiced by the medical professionals during those times; however, traditional herbal healers persisted outside the mainstream medical system.

During the eighth century a medical school was established in Salerno, Italy, where the herbal knowledge accumulated by Arab physicians was preserved. The Arabian Muslims conducted extensive research on medicinal herbs found in Europe, Persia, India, and the Far East. Arab businessmen opened the first herbal pharmacies early in the ninth century. The *Leech Book of Bald*, the work of a Christian monk, was compiled in the tenth century. It preserved important medical writings that had survived from the work of physicians in ancient Greece and Rome.

The Middle Ages in Europe was a time of widespread death from plagues and pestilence. The Black **Plague** of 1348, particularly, and other health catastrophes in later years, claimed so many lives that survivors began to lose faith in the dominant Galenic medical system. Fortunately, the knowledge of traditional herbal medicine had not been lost. Medieval

WWW.BOOKBAZ.IR

monks who cultivated extensive medicinal gardens on the monastery grounds, also patiently copied the ancient herbal and medical texts. Folk medicine as practiced in Europe by traditional healers persisted, even though many women herbalists were persecuted as witches and enemies of the Catholic church and their herbal arts were suppressed.

The growing spice trade and explorations to the New World introduced exotic plants, and a whole new realm of botanical medicines became available to Europeans. Following the invention of the printing press in the fifteenth century, a large number of herbal texts, also simply called herbals, became available for popular use. Among them were the beautifully illustrated works of the German botanists Otto Brunfels and Leonhard Fuchs published in 1530 and the Dutch herbal of Belgian physician Rembert Dodoens, a popular work that was later reproduced in English. In 1597, the physician and gardener John Gerard published one of the most famous of the English herbal, still in print today. Gerard's herbal, known as *The Herball or General Historie of Plantes* was not an original work. Much of the content was taken from the translated text of his Belgian predecessor Dodoens. Gerard did, however, include descriptions of some of the more than 1,000 species of rare and exotic plants and English flora from his own garden.

The correspondence of astrology with herbs was taught by Arab physicians who regarded astrology as a science helpful in the selection of medicines and in the treatment of diseases. This approach to western herbalism was particularly evident in the herbal texts published in the sixteenth and seventeenth centuries. One of the most popular and controversial English herbals is *The English Physician Enlarged* published in 1653. The author, Nicholas Culpeper, was an apothecary by trade. He also published a translation of the Latin language *London Pharmacopoeia* into English. Culpeper was a nonconformist in loyalist England, and was determined to make medical knowledge more accessible to the apothecaries, the tradesmen who prescribed most of the herbal remedies. Culpeper's herbal was criticized by the medical establishment for its mix of magic and astrology with botanical medicine, but it became one of the most popular compendiums of botanical medicine of its day. Culpeper also accepted the so-called "Doctrine of Signatures," practiced by medieval monks in their medicinal gardens. This theory teaches that the appearance of plants is the clue to their curative powers. Plants were chosen for treatment of particular medical conditions based on their associations with the four natural elements and with a planet or sign. The place where the plant grows, its dominant physical feature, and the smell and taste of an herb determined the plant's signature. Culpeper's herbal is still in print in facsimile copies, and some pharmocognosists and herbalists in the twenty-first century voice the same criticisms that Culpeper's early critics did.

European colonists brought their herbal knowledge and plant specimens to settlements in North America where they learned from the indigenous Americans how to make use of numerous nutritive and medicinal plants, native to the New World. Many European medicinal plants escaped cultivation from the early settlements and have become naturalized throughout North America. The first record of Native American herbalism is found in the manuscript of the native Mexican Indian physician, Juan Badianus published in 1552. The American Folk tradition of herbalism developed as a blend of traditional European medicine and Native American herbalism. The pioneer necessity for self-reliance contributed to the perseverance of folk medicine well into the twentieth century.

In Europe in the seventeenth century, the alchemist Paracelsus changed the direction of western medicine with the introduction of chemical and mineral medicines. He was the son of a Swiss chemist and physician. Paracelsus began to apply chemicals, such as arsenic, mercury, sulfur, iron, and copper sulfate to treat disease. His chemical approach to the treatment of disease was a forerunner to the reliance in the twentieth century on chemical medicine as the orthodox treatment prescribed in mainstream medical practice.

The nineteenth and twentieth centuries brought a renewed interest in the practice of Western herbalism and the development of natural therapies and health care systems that ran counter to the mainstream methods of combating disease symptoms with synthetic pharmaceuticals.

In the late eighteenth century, the German physician Samuel Hahnemann developed a system of medicine known as homeopathy. This approach to healing embraces the philosophy of "like cures like." Homeopathy uses extremely diluted solutions of herbs, animal products, and chemicals that are believed to hold a "trace memory" or energetic imprint of the substance used. Homeopathic remedies are used to amplify the patient's symptoms with remedies that would act to produce the same symptom in a healthy person. Homeopathy holds that the symptoms of illness are evidence of the body's natural process of healing and eliminating the cause of the disease.

In 1895, the European medical system known as Naturopathy was introduced to the North America.

Like homeopathy, this medical approach is based on the Hippocratic idea of eliminating disease by assisting the body's natural healing abilities. The naturopath uses nontoxic methods to assist the body's natural healing processes, including **nutritional supplements**, herbal remedies, proper diet, and **exercise** to restore health.

Western herbalism is regaining popularity at a time when the world is assaulted by the stress of overpopulation and development that threatens the natural biodiversity necessary for these valuable medicinal plants to survive. The American herb market is growing rapidly and increasing numbers of individuals are choosing alternative therapies over the mainstream allopathic Western medicine. Consumers spend more than $7 billion a year on herbal products. An estimated 2,400 acres of native plant habitat are lost to development every day. As much as 29% of all plant life in North America is in danger of extinction, including some of the most important native medicinal plants, according to the 1997 World Conservation Union Red List of Threatened Plants.

Though research into the efficacy and safety of traditional herbal remedies is increasing, it has been limited by the high costs of clinical studies and laboratory research, and by the fact that whole plants and their constituents are not generally patentable (therefore, there is no drug profit after market introduction). Outside the United States, herbalism has successfully combined with conventional medicine and in some countries is fully integrated into the nation's health care systems. At the beginning of the twenty-first century, 80% of the world's population continues to rely on herbal treatments. The World Health Organization, an agency of the United Nations, promotes traditional herbal medicine for treatment of many local health problems, particularly in the third world where it is affordable and already well-integrated into the cultural fabric.

In the United States, the re-emergence of interest in holistic approaches to health care is evident. Citizens are demanding access to effective, safe, low-cost, natural medicine. Legislative and societal change is needed, however, before natural therapies can be fully integrated into the orthodox allopathic health care system and provide patients with a wide range of choices for treatment. If the current trend continues, U.S. citizens will benefit from a choice among a variety of safe and effective medical treatments.

Herbs are generally defined as any plant or plant part that may be used for medicinal, nutritional, culinary, or other beneficial purposes. The active constituents of plants (if known) may be found in varying amounts in the root, stem, leaf, flower, and fruit, etc. of the plant. Herbs may be classified into many different categories. Some western herbalists categorize herbal remedies according to their strength, action, and characteristics. Categories may include sedatives, stimulants, **laxatives**, febrifuges (to reduce **fever**), and many others. One system of classification is based on a principle in traditional Chinese medicine that categorizes herbs into four classes: tonics, specifics, heroics, and cleansers and protectors. Within these broad classifications are the numerous medicinal actions of the whole herb, which may be due to a specific chemical or combination of chemicals in the plant.

- Tonics. Herbs in this classification are also known as alteratives in Western herbalism. They are generally mild in their action and act slowly in the body, providing gentle stimulation and nutrition to specific organs and systems. Tonic herbs act over time to strengthen and nourish the whole body. These herbs are generally safe and may be used regularly, even in large quantities. These tonic herbs are known as "superior" remedies in traditional Chinese medicine. The therapeutic dose of tonic remedies is far removed from the possible toxic dose. American ginseng is an example of a tonic herb.
- Specifics. Herbs in this classification are strong and specific in their therapeutic action. They are generally used for short periods of time in smaller dosages to treat acute conditions. Herbs classified as specifics are not used beyond the therapeutic treatment period. Echinacea is a specific herb.
- Heroic. These herbs offer high potency but are potentially toxic and should not be used in self-treatment. Because the therapeutic dosage may be close to the lethal dosage, these herbs are presented cautiously and closely monitored or avoided by trained clinicians. They should not be used continuously or without expert supervision. Poke (*Phytolacca americana*) is an example of a heroic remedy.
- Cleansers and protectors. These herbs, plants, and plant tissues remove wastes and pollutants, while minimally affecting regular body processes. An example of a cleanser is pectin. Pectins are the water soluble substances that bind cell walls in plant tissues, and some believe that they help remove heavy metals and environmental toxins from the body.

Preparations

Herbal preparations are commercially available in a variety of forms, including tablets or capsules,

WWW.BOOKBAZ.IR

KEY TERMS

In vitro—A biological reaction occurring in a laboratory apparatus.

In vivo—Occurring in a living organism.

Phyto-, as in phytochemical, phytomedicinal, and phytotherapy—Meaning, or pertaining to, a plant or plants.

Wildcrafting—Gathering of herbs or other natural materials.

tinctures, teas, fluid extracts, douches, washes, suppositories, dried herbs, and many other forms. The medicinal properties of herbs are extracted from the fresh or dried plant parts by the use of solvents appropriate to the particular herb. Alcohol, oil, water, vinegar, glycerin, and propylene glycol are some of the solvents used to extract and concentrate the medicinal properties. Steam distillation and cold-pressing techniques are used to extract the essential oils. The quality of any herbal remedy and the potency of the phytochemicals found in the herb depends greatly on the conditions of weather and soil where the herb was grown, the timing and care in harvesting, and the manner of preparation and storage.

Precautions

Herbal remedies prepared by infusion, decoction, or alcohol tincture from the appropriate plant part, such as the leaf, root, or flower, are generally safe when ingested in properly designated therapeutic dosages. However, many herbs have specific contraindications for use when certain medical conditions are present. Not all herbal remedies may be safely administered to infants or small children. Many herbs are not safe for use by pregnant or lactating women. Some herbs are toxic, even deadly, in large amounts, and there is little research on the chronic toxicity that may result from prolonged use. Herbal remedies are sold in the United States as dietary supplements and are not regulated for content or efficacy. Self-diagnosis and treatment with botanical medicinals may be risky. A consultation with a clinical herbalist, Naturopathic physician, or certified clinical herbalist is prudent before undertaking a course of treatment.

Essential oils are highly concentrated and should not be ingested as a general rule. They should also be diluted in water or in a non-toxic carrier oil before application to the skin to prevent **contact dermatitis** or photo-sensitization. The toxicity of the concentrated essential oil varies depending on the chemical constituents of the herb.

The American Professor of Pharmacognosy, Varro E. Tyler, believes that "herbal chaos" prevails in the United States with regard to herbs and phytomedicinals. In part he blames the herb producers and marketers of crude herbs and remedies for what he terms unproven hyperbolic, poor quality control, deceptive labeling, resistance to standardization of dosage forms, and continued sale of herbs determined to be harmful.

Side effects

Herbs have a variety of complex phytochemicals that act on the body as a whole or on specific organs and systems. Some of these chemical constituents are mild and safe, even in large doses. Other herbs contain chemicals that act more strongly and may be toxic in large doses or when taken continuously. **Drug interactions** are possible with certain herbs when combined with certain pharmaceutical drugs. Some herbs are tonic in a small amount and toxic in larger dosages.

Research and general acceptance

Western herbalism is experiencing a revival of popular and professional interest. The number of training schools and qualified herbal practitioners is growing to meet the demand. Western herbalism is incorporated into the medical practice of licensed Naturopathic doctors, who receive special training in clinical herbalism. Folk herbalists, heir to the continuing oral traditions passed from generation to generation in many rural areas, as well as amateur, self-taught herbalists, keep the practice of botanical medicine alive at the grassroots level. Traditional Western herbalism relies on traditional use and *materia medica*, folk wisdom, and recent clinical research and advances in the extraction processes. These advances provide increased quality control on the concentration and potency of the active ingredients. Western physicians, educated in allopathic medicine, typically receive no training in the use of herbs. These doctors rely on pharmaceutical drugs for their patients, and some cite the following reasons for continuing to do so: lack of standardized dosages, lack of quality control in the preparation of herbal medicinals, and the dearth of clinical research verifying the safety and effectiveness of many traditional herbal remedies.

Herbalism is widely practiced throughout Europe, particularly in England, France, Italy, and Germany, where phytomedicinals are available in prescription form and as over-the-counter remedies. In Germany, plant medicines are regulated by a special government body known as the Commission E. In the United States, however, despite increasing popularity, traditional herbalism is not integrated into the allopathic medical system. Phytomedicinals are sold as dietary supplements rather than being adequately researched and recognized as safe and effective drugs. The Dietary Supplement Health and Education Act of 1994 circumvented a U.S. Food and Drug Administration (FDA) effort to effectively remove botanicals from the marketplace and implement regulations restricting sale. Massive popular outcry against the proposed regulations on the sale of herbs and phytomedicinals resulted in this Congressional action. In 2000, U.S. President Bill Clinton, by executive order, created the White House Commission on Alternative Medicine in an effort to hold alternative medicine therapies "to the same standard of scientific rigor as more traditional health care interventions." That Commission is charged with recommending federal guidelines and legislation regarding the use of alternative medical therapies in the twenty-first century.

Hereditary fructose intolerance

Definition

Hereditary fructose intolerance is an inherited condition where the body does not produce the chemical needed to break down fructose (fruit sugar).

Description

Fructose is a sugar found naturally in fruits, vegetables, honey, and table sugar. Fructose intolerance is a disorder caused by the body's inability to produce an enzyme called aldolase B (also called fructose 1-phosphate aldolase) that is necessary for absorption of fructose. The undigested fructose collects in the liver and kidneys, eventually causing liver and kidney failure. One person in about 20,000 is born with this disorder. It is reported more frequently in the United States and Northern European countries than in other parts of the world. It occurs with equal frequency in males and females.

Causes and symptoms

Fructose intolerance is an inherited disorder passed on to children through their parents' genes. Both the mother and father have the gene that causes the condition, but may not have symptoms of fructose intolerance themselves. (This is called an autosomal recessive pattern of inheritance.) The disorder will not be apparent until the infant is fed formula, juice, fruits, or baby foods that contain fructose. Initial symptoms include **vomiting**, **dehydration**, and unexplained **fever**. Other symptoms include extreme thirst and excessive urination and sweating. There will also be a loss of appetite and a failure to grow. **Tremors** and seizures caused by low blood sugar can occur. The liver becomes swollen and the patient becomes jaundiced with yellowing of the eyes and skin. Left untreated, this condition can lead to **coma** and death.

Diagnosis

Urine tests can be used to detect fructose sugar in the urine. Blood tests can also be used to detect hyperbilirubinemia and high levels of liver enzymes in the blood. A **liver biopsy** may be performed to test for levels of enzymes present and to evaluate the extent of damage to the liver. A fructose-loading test where a dose of fructose is given to the patient in a well-controlled hospital or clinical setting may also be used to confirm fructose intolerance. Both the biopsy and the loading test can be very risky, particularly in infants that are already sick.

WWW.BOOKBAZ.IR

KEY TERMS

Aldolase B—Also called fructose 1-phosphate aldolase, this chemical is produced in the liver, kidneys, and brain. It is needed for the breakdown of fructose, a sugar found in fruits, vegetables, honey, and other sweeteners.

Hyperbilirubinemia—A condition where there is a high level of bilirubin in the blood. Bilirubin is a natural by-product of the breakdown of red blood cells; a high level of bilirubin may indicate a problem with the liver.

Liver biopsy—A surgical procedure where a small piece of the liver is cut out for examination. A needle or narrow tube may be inserted either directly through the skin and muscle or through a small incision and passed into the liver for collection of a sample of liver tissue.

Treatment

Once diagnosed, fructose intolerance can be successfully treated by eliminating fructose from the diet. Patients usually respond within three to four weeks and can make a complete recovery if fructose-containing foods are avoided. Early recognition and treatment of the disease is important to avoid damage to the liver, kidneys, and small intestine.

Prognosis

If the condition is not recognized and the diet is not well controlled, death can occur in infants or young children. With a well-controlled diet, the child can develop normally.

Prevention

Carriers of the gene for hereditary fructose intolerance can be identified through DNA analysis. Anyone who is known to carry the disease or who has the disease in his or her family can benefit from **genetic counseling**. Since this is a hereditary disorder, there is currently no known way to prevent it other than assisting at-risk individuals with family planning and reproductive decisions.

Hereditary hemorrhagic telangiectasia

Definition

Hereditary hemorrhagic telangiectasia is an inherited condition characterized by abnormal blood vessels that are delicate and prone to bleeding. Hereditary hemorrhagic telangiectasia is also known as Rendu-Osler-Weber disease.

Description

The term telangiectasia refers to a spot formed, usually on the skin, by a dilated capillary or terminal artery. In hereditary hemorrhagic telangiectasia these spots occur because the blood vessel is fragile and bleeds easily. The bleeding may appear as small, red or reddish-violet spots on the face, lips, inside the mouth and nose or the tips of the fingers and toes. Other small telangiectasias may occur in the digestive tract.

Unlike **hemophilia**, where bleeding is caused by an ineffective clotting mechanism in the blood, bleeding in hereditary hemorrhagic telangiectasia is caused by fragile blood vessels. However, like hemophilia, bleeding may be extensive and can occur without warning.

Causes and symptoms

Hereditary hemorrhagic telangiectasia, an autosomal dominant inherited disorder, occurs in one in 50,000 people.

Recurrent nosebleeds are a nearly universal symptom of this condition. Usually the nosebleeds begin in childhood and become worse with age. The skin changes begin at **puberty**, and the condition becomes progressively worse until about 40 years of age, when it stabilizes.

KEY TERMS

Autosomal dominant—A pattern of inheritance in which the dominant gene on any non-sex chromosome carries the defect.

Chromosome—A threadlike structure in the cell that transmits genetic information.

Diagnosis

The physician will look for red spots on all areas of the skin, but especially on the upper half of the body, and in the mouth and nose and under the tongue.

Treatment

There is no specific treatment for hereditary hemorrhagic telangiectasia. The bleeding resulting from the condition can be stopped by applying compresses or direct pressure to the area. If necessary, a laser can be used to destroy the vessel. In severe cases, the leaking artery can be plugged or covered with a graft from normal tissue.

Prognosis

In most people, recurrent bleeding results in an iron deficiency. It is usually necessary to take iron supplements.

Prevention

Hereditary hemorrhagic telangiectasia is an inherited disorder and cannot be prevented.

Hernia

Definition

Hernia is a general term used to describe a bulge or protrusion of an organ through the structure or muscle that normally contains it.

Demographics

The frequency of hernias varies greatly depending on the type of hernia. Hernias tend to be more common in the elderly than in younger individuals. Hernias also are more common in infants and children, often caused by the abdominal wall not closing completely after birth.

Hiatal hernias are very common, although most do not produce serious symptoms and many individuals never even know they have one. About 10% of individuals under the age of 40 have hiatal hernias. This number increases with age, with about 70% of individuals over age 70 having this type of hernia.

Abdominal hernias are more common in males than in females. About 25% of men have an inguinal hernia at some time in their lives, and only about 2% of women ever have one. Over 1 million surgeries are performed each year to repair abdominal hernias.

Description

There are many different types of hernias. The most familiar type occurs in the abdomen when part of the intestine protrudes through the abdominal wall. This may occur in different areas and, depending on the location, the hernia is given a different name.

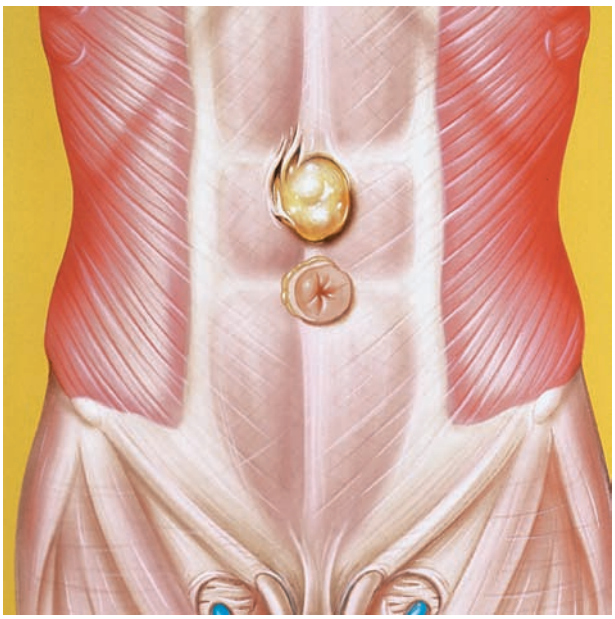
An inguinal hernia appears as a bulge in the groin and may come and go depending on the position of the person or their level of physical activity. It can occur with or without **pain**. In men, the protrusion may descend into the scrotum. Inguinal hernias account for 80% of all hernias and are more common in men.

Femoral hernias are similar to inguinal hernias but appear as a bulge slightly lower. They are more common in women and are often caused by the strain that **pregnancy** puts on the abdominal area.

A ventral hernia is also called an incision hernia because it generally occurs as a bulge in the abdomen at the site of an old surgical scar. It is caused by thinning or stretching of scar tissue. It occurs more frequently in people who are obese or pregnant.

An umbilical hernia appears as a soft bulge at the navel (umbilicus). It is caused by a weakening of the

WWW.BOOKBAZ.IR



An illustration of an epigastric (abdominal) hernia in an adult male. The torso is shown with its skin removed. Epigastric hernia is caused commonly by a congenital weakness in muscles of the central upper abdomen; the intestine bulges out through the muscle at a point between the navel and breastbone. *(John Bavosi/Photo Researchers, Inc.)*

area or an imperfect closure of the area in infants. This type of hernia is more common in women due to pregnancy and in Chinese and African American infants. Some umbilical hernias in infants disappear without treatment within the first year.

A hiatal or diaphragmatic hernia is different from abdominal hernias in that it is not visible on the outside of the body. With a **hiatal hernia**, the stomach bulges upward through the muscle that separates the chest from the abdomen (the diaphragm). This type of hernia occurs more often in women than in men, and it is treated differently from other types of hernias.

Causes and symptoms

Most hernias result from a weakness in the abdominal wall. In many cases an infant is born with this weakness (congenital), and in other cases weakness can develop later in life. Any increase in pressure in the abdomen, such as recurring coughing, straining, heavy lifting, or pregnancy, can be a considered a causative factor in developing an abdominal hernia. **Obesity** or recent excessive weight loss, as well as **aging** and previous surgery, are also risk factors.

Most abdominal hernias appear suddenly when the abdominal muscles are strained. The individual may feel tenderness, a slight burning sensation, or a feeling of heaviness in the bulge. It may be possible for the individual to push the hernia back into place with gentle pressure, or the hernia may disappear by itself when the person reclines. Being able to push the hernia back is called reducing it. On the other hand, some hernias cannot be pushed back into place and are termed incarcerated or irreducible.

A hiatal hernia may also be caused by obesity, pregnancy, aging, or previous surgery. About 50% of all people with hiatal hernias do not have any symptoms. If symptoms exist, they usually include **heartburn** 30–60 minutes following a meal. There may be some mid chest pain due to gastric acid from the stomach being pushed up into the esophagus (gastric reflux). The pain and heartburn usually are worse when lying down. Frequent belching and feelings of abdominal fullness may also be present.

Diagnosis

Generally, abdominal hernias need to be seen and felt to be diagnosed. Usually, the hernia will increase in size with an increase in abdominal pressure, so the doctor may ask the person to **cough** while he or she feels the area. Once a diagnosis of an abdominal hernia is made, the doctor will refer the individual to a surgeon for a consultation. Surgery provides the only cure for a hernia through the abdominal wall.

With a hiatal hernia, the preliminary diagnosis is based on the symptoms reported by the patient. The doctor may then order tests to confirm the diagnosis. One possible test is called a barium swallow test. During this procedure, the individual drinks a chalky white barium solution and then undergoes an abdominal x ray. The barium causes any protrusion through the diaphragm to show up more clearly on the x ray. Hiatal hernias often are diagnosed using **endoscopy**. This procedure is done by a gastroenterologist (a specialist in digestive diseases). During an endoscopy the person is given an intravenous sedative and a small tube is inserted through the mouth, then into the esophagus and stomach where the doctor can look at the hernia using a small tube or camera. The procedure takes about 30 minutes and usually causes no discomfort. It is done on an outpatient basis.

Treatment

Once an abdominal hernia occurs it tends to increase in size. Some patients with abdominal hernias take a watch and wait approach before deciding on surgery. In these cases, they must avoid strenuous physical activity such as heavy lifting or straining with **constipation**. They may also wear a truss, which

KEY TERMS

Endoscopy—A diagnostic procedure in which a tube is inserted through the mouth, into the esophagus and stomach. It is used to visualize various digestive disorders, including hiatal hernias.

Herniorrhaphy—Surgical repair of a hernia.

Incarcerated hernia—A hernia that cannot be reduced, or pushed back into place inside the abdominal wall.

Laparoscopic surgery—A minimally invasive surgery in which a camera and surgical instruments are inserted through a small incision.

Reducible hernia—A hernia that can be gently pushed back into place or that disappears when the person lies down.

Strangulated hernia—A hernia that is so tightly incarcerated outside the abdominal wall that the intestine is blocked and the blood supply to that part of the intestine is cut off.

is a support worn like a belt to keep a small hernia from protruding. People can tell if their hernia is getting worse if they develop severe constant pain, **nausea and vomiting**, or if the bulge does not return to normal when lying down or when they try to gently push it back in place. In these cases they, should consult their doctor immediately. In most cases, surgery is eventually required to correct the hernia.

Surgery

There are risks to not surgically repairing a hernia. Left untreated, a hernia may become incarcerated, which means it can no longer be reduced or pushed back into place. With an incarcerated hernia, the intestine become trapped, or strangulated, outside the abdomen. This can lead to a blockage in the intestine. If strangulation is severe, it may cut off the blood supply to the intestine and part of the intestine will die. Because of the risk of tissue death (**necrosis**) and **gangrene**, and because the hernia can block food from moving through the bowel, a strangulated hernia is a medical emergency requiring immediate surgery. Repairing a hernia before it becomes incarcerated or strangulated is much safer than waiting until complications develop.

Surgical repair of a hernia is called a herniorrhaphy. The surgeon will push the bulging part of the intestine back into place and sew the overlying muscle back together. When the muscle is not strong enough, the surgeon may reinforce it with a synthetic mesh.

Surgery can be done on an outpatient basis. It usually takes 30 minutes in children and 60 minutes in adults. It can be done under either local or general **anesthesia** and is frequently done laparoscopically. In this type of surgery, a tube that allows visualization of the abdominal cavity is inserted through a small puncture wound. Several small punctures are made to allow surgical instruments to be inserted. This type of surgery avoids a larger incision and significantly reduces the time required for recovery.

Hiatal hernias normally are treated without surgery. The focus of the treatment is to reduce the symptoms associated with **gastroesophageal reflux disease** (GERD) associated with the hernia. Treatments include:

- avoiding reclining after meals
- avoiding spicy foods, acidic foods, alcohol, and tobacco
- eating small, frequent, bland meals
- eating a high-fiber diet

Several types of medications can help manage the symptoms of gastric reflux and heartburn associated with hiatal hernia. **Antacids** are used to neutralize gastric acid and decrease heartburn. Drugs that reduce the amount of acid produced in the stomach (H-2 blockers) are also used. This class of drugs includes famotidine (Pepcid), cimetidine (Tagamet), and ranitidine (Zantac). Omeprazole (Prilosec) is a proton pump inhibitor (PPI) drug, which is another class of drugs that suppress gastric acid secretion and are used for symptoms associated with hiatal hernias. Another option may be metoclopramide (Reglan), a drug that increases the tone of the muscle around the esophagus and causes the stomach to empty more quickly. This drug can have serious side effects.

Alternatives

Visceral manipulation, done by a trained therapist, can help replace the stomach to its proper positioning. An alternative to H2 blocker and PPI drugs is deglycyrrhizinated licorice (DGL). This helps balance stomach acid by improving the protective substances that line the stomach and intestines and by improving blood supply to these tissues. DGL does not interrupt the normal function of stomach acid.

As with traditional therapy, dietary modifications are important. Small, frequent meals will keep pressure down on the esophageal sphincter. Raising the head of the bed several inches with blocks or books can help with both the quality and quantity of sleep.

WWW.BOOKBAZ.IR

Prognosis

Abdominal hernias generally do not recur in children but can recur in up to 10% of adult patients. Surgery is considered the only cure, and the prognosis is excellent if the hernia is corrected before it becomes strangulated.

Hiatal hernias are treated successfully with medication and diet modifications 85% of the time.

Prevention

Some hernias can be prevented by maintaining a reasonable weight, not **smoking**, avoiding heavy lifting, preventing constipation, and following a moderate **exercise** program to maintain good abdominal muscle tone.

Hernia repair

Definition

Hernia repair is a surgical procedure to return an organ that protrudes through a weak area of muscle to its original position.

Purpose

Hernias occur when a weakness in the wall of the abdomen allows an organ, usually the intestines, to bulge out of place. Hernias may result from a genetic predisposition toward this weakness. They can also be the result of weakening the muscle through improper **exercise** or poor lifting techniques. Both children and adults get hernias. Some are painful, while others are not.

There are three levels of hernias. An uncomplicated hernia is one where the intestines bulge into the peritoneum (the membrane lining the abdomen), but they can still be manipulated back into the body (although they do not stay in place without corrective surgery). This is termed a reducible hernia.

If the intestines bulge through the hernia defect and become trapped, this is called an incarcerated hernia. If the blood supply to an incarcerated hernia is shut off, the hernia is called a strangulated hernia. Strangulated hernias can result in **gangrene**.

Both incarcerated and strangulated hernias are medical emergencies and require emergency surgery to correct. For this reason, doctors generally recommend the repair of an uncomplicated hernia, even if it causes no discomfort to the patient.

Precautions

Hernia repair can be performed under local, regional, or general **anesthesia**. The choice depends on the age and health of the patient and the type of hernia. Generally, hernia repair is very safe surgery, but as with any surgery the risk of complications increases if the patient smokes, is obese, is very young or very old, uses alcohol heavily, or uses illicit drugs.

Description

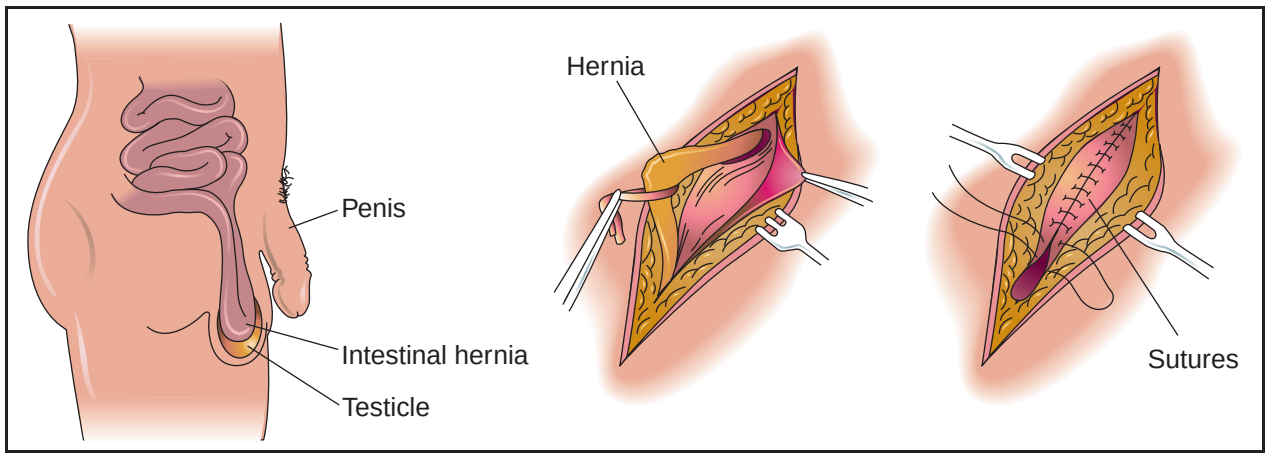
Hernia repairs are performed in a hospital or outpatient surgical facility by a general surgeon. Depending on the patient's age, health, and the type of hernia, he or she may be able to go home the same day or may remain hospitalized for up to three to five days.

There are two types of hernia repair. A herniorrhaphy is used for simpler hernias. The intestines are returned to their proper place and the defect in the abdominal wall is mended. A hernioplasty is used for larger hernias. In this procedure, plastic or steel mesh is added to the abdominal wall to repair and reinforce the weak spot.

There are five kinds of common hernia repairs. They are named for the part of the body closest to the hernia, or bulge.

Femoral hernia repair

This procedure repairs a hernia that occurs in the groin where the thigh meets the abdomen. It is called a femoral hernia repair because it is near the spot where



In this inguinal hernia repair, an incision is made in the abdomen. The hernia is located, and the intestines are returned to the abdomen. The abdominal wall is then sutured together to close any space and reinforce the weak area. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

the femoral artery and vein pass from the leg into the trunk of the body. Sometimes this type of hernia creates a noticeable bulge.

An incision is made in the groin area. The tissues are separated from the hernia sac, and the intestines are returned to the abdomen. The area is often reinforced with webbing before it is sewn shut. The skin is closed with sutures or metal clips that can be removed in about one week.

Inguinal hernia repair

Inguinal hernia repair closes a weakness in the abdominal wall that is near the inguinal canal, the spot where the testes descend from the body into the scrotum. This type of hernia occurs in about 2% of adult males.

An incision is made in the abdomen, then the hernia is located and repaired. The surgeon must be alert not to injure the spermatic cord, the testes, or the blood supply to the testes. If the hernia is small, it is simply repaired. If it is large, the area is reinforced with mesh to prevent a recurrence. External skin sutures can be removed in about a week. Patients should not resume sexual activity until being cleared by their doctor.

Umbilical hernia repair

This procedure repairs a hernia that occurs when the intestines bulge through the abdomen wall near the navel. Umbilical hernias are most common in infants.

An incision is made near the navel. The hernia is located and the intestines are returned to the abdomen. The peritoneum is closed, then the large abdominal muscle is pulled over the weak spot in such a way as to reinforce the area. External sutures or skin clips can be removed in about 10 days.

Incisional hernia repair

Incisional hernias occur most frequently at the site of a scar from earlier abdominal surgery. Once again, the abdomen is opened and the intestines returned to their proper place. The area is reinforced with mesh, and the abdominal wall is reconstructed to prevent another hernia from developing. External sutures can be removed in about a week.

Hiatal hernia

A **hiatal hernia** repair is slightly different from the other hernias, because it corrects a weakness or opening in the diaphragm, the muscle that separates the chest cavity from the abdominal cavity. This surgery is done to prevent the stomach from shifting up into the chest cavity and to prevent the stomach from spilling gastric juices into the esophagus, causing **pain** and scarring.

An incision is made in the abdomen or chest, and the hole or weakness in the diaphragm is located and repaired. The top of the stomach is wrapped around the bottom of the esophagus, and they are sutured together to hold the stomach in place. Sometimes the vagus nerve is cut in order to decrease the amount of acid the stomach produces. External sutures can be removed in about one week. This type of hernia repair often requires a longer hospital stay than the other types, although techniques are being improved that reduce invasiveness of the surgery and the length of the hospital stay.

WWW.BOOKBAZ.IR

KEY TERMS

Endoscopy—A procedure in which an instrument containing a camera is inserted into the gastrointestinal tract so that the doctor can visually inspect the gastrointestinal system.

Gangrene—Death and decay of body tissue because the blood supply is cut off. Tissues that have died in this way must be surgically removed.

Peritoneum—The transparent membrane lining the abdominal cavity that holds organs such as the intestines in place.

Preparation

Before the operation, the patient will have blood and urine collected for testing. X rays are taken of the affected area. In a hiatal hernia, an **endoscopy** (a visual inspection of the organs) is done.

Patients should meet with the anesthesiologist before the operation to discuss any medications or conditions that might affect the administration of anesthesia. Patients may be asked to temporarily discontinue certain medications. The day of the operation, patients should not eat or drink anything. They may be given an enema to clear the bowels.

Aftercare

Patients should eat a clear liquid diet until the gastrointestinal tract begins functioning again. Normally this is a short period of time. After that, they are free to eat a healthy, well-balanced diet of their choice. They may bathe normally, using a gentle, unscented soap. An antibiotic ointment may be prescribed for the incision. After the operation, a hard ridge will form along the incision line. With time, this ridge softens and becomes less noticeable. Patients who remain in the hospital will have blood drawn for follow-up studies.

Patients should begin easy activities, such as walking, as soon as they are comfortable, but should avoid strenuous exercise for four to six weeks, and especially avoid heavy lifting. Learning and practicing proper lifting techniques is an important part of patient education after the operation. Patients may be given a laxative or stool softener so that they will not strain to have bowel movements. They should discuss with their doctor when to resume driving and sexual activity.

Risks

As with any surgery, there exists the possibility of excessive bleeding and infection after the surgery. In inguinal and femoral hernia repair, a slight risk of damage to the testicles or their blood supply exists for male patients. Accidental damage may be caused to the intestinal tract, but complications are rare.

Results

The outcome of surgery depends on the age and health of the patient and on the type of hernia. Although most hernias can be repaired without complications, hernias recur in 10–20% of people who have had hernia surgery.

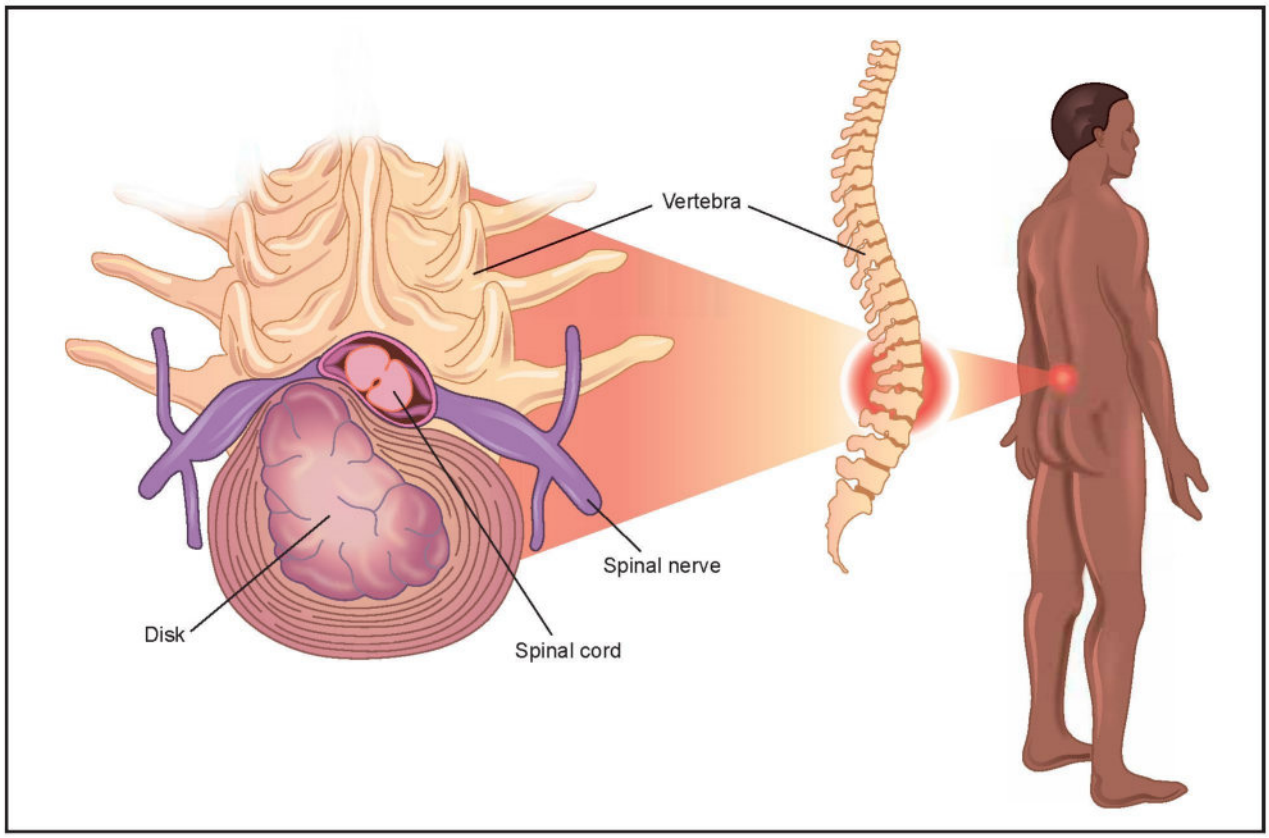
Herniated disk

Definition

Disk herniation is a rupture of fibrocartilagenous material (annulus fibrosis) that surrounds the intervertebral disk. This rupture involves the release of the disk's center portion containing a gelatinous substance called the nucleus pulposus. Pressure from the vertebrae above and below may cause the nucleus pulposus to be forced outward, placing pressure on a spinal nerve and causing considerable **pain** and damage to the nerve. This condition most frequently occurs in the lumbar region and is also commonly called herniated nucleus pulposus, prolapsed disk, ruptured intervertebral disk, or slipped disk.

Description

The spinal column is made up of 26 vertebrae that are joined together and permit forward and backward bending, side bending, and rotation of the spine. Five distinct regions comprise the spinal column, including the cervical (neck) region, thoracic (chest) region, lumbar (low back) region, sacral, and coccygeal (tailbone) region. The cervical region consists of seven vertebrae, the thoracic region includes 12 vertebrae, and the lumbar region contains five vertebrae. The sacrum is



A herniated disk refers to the rupture of fibrocartilagenous material, called the annulus fibrosis, that surrounds the intervertebral disk. When this occurs, pressure from the vertebrae above and below may force the disk's center portion, a gel-like substance, outward, placing additional pressure on the spinal nerve and causing pain and damage to the nerve. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

composed of five fused vertebrae, which are connected to four fused vertebrae forming the coccyx. Intervertebral disks lie between each adjacent vertebra.

Each disk is composed of a gelatinous material in the center, called the nucleus pulposus, surrounded by rings of a fiberous tissue (annulus fibrosus). In disk herniation, an intervertebral disk's central portion herniates or slips through the surrounding annulus fibrosus into the spinal canal, putting pressure on a nerve root. Disk herniation most commonly affects the lumbar region between the fifth lumbar vertebra and the first sacral vertebra. However, disk herniation can also occur in the cervical spine. The incidence of cervical disk herniation is most common between the fifth and sixth cervical vertebrae. The second most common area for cervical disk herniation occurs between the sixth and seventh cervical vertebrae. Disk herniation is less common in the thoracic region.

Predisposing factors associated with disk herniation include age, gender, and work environment. The peak age for occurrence of disk herniation is between 20–45 years of age. Studies have shown that males are more commonly affected than females in lumbar disk herniation by a 3:2 ratio. Prolonged exposure to a bent-forward work posture is correlated with an increased incidence of disk herniation.

There are four classifications of disk pathology:

- A protrusion may occur where a disk bulges without rupturing the annulus fibrosis.
- The disk may prolapse where the nucleus pulposus migrates to the outermost fibers of the annulus fibrosis.
- There may be a disk extrusion, which is the case if the annulus fibrosis perforates and material of the nucleus moves into the epidural space.
- The sequestrated disk may occur as fragments from the annulus fibrosis and nucleus pulposus are outside the disk proper.

Causes and symptoms

Any direct, forceful, and vertical pressure on the lumbar disks can cause the disk to push its fluid contents into the vertebral body. Herniated nucleus

WWW.BOOKBAZ.IR

pulposus may occur suddenly from lifting, twisting, or direct injury, or it can occur gradually from degenerative changes with episodes of intensifying symptoms. The annulus may also become weakened over time, allowing stretching or tearing and leading to a disk herniation. Depending on the location of the herniation, the herniated material can also press directly on nerve roots or on the spinal cord, causing a shock-like pain (**sciatica**) down the legs, weakness, numbness, or problems with bowels, bladder, or sexual function.

Diagnosis

Several radiographic tests are useful for confirming a diagnosis of disk herniation and locating the source of pain. These tests also help the surgeon indicate the extent of the surgery needed to fully decompress the nerve. X rays show structural changes of the lumbar spine. **Myelography** is a special x ray of the spine in which a dye or air is injected into the patient's spinal canal. The patient lies strapped to a table as the table tilts in various directions and spot x rays are taken. X rays showing a narrowed dye column in the intervertebral disk area indicate possible disk herniation.

A computed tomography scan (CT or CAT scan) exhibits the details of pathology necessary to obtain consistently good surgical results. **Magnetic resonance imaging** (MRI) analysis of the disks can accurately detect the early stages of disk **aging** and degeneration. Electomyograms (EMGs) measure the electrical activity of the muscle contractions and possibly show evidence of nerve damage. An EMG is a powerful tool for assessing muscle **fatigue** associated with muscle impairment with **low back pain**.

Treatment

Drugs

Unless serious neurologic symptoms occur, herniated disks can initially be treated with pain medication and up to 48 hours of bed rest. There is no proven benefit from resting more than 48 hours. Patients are then encouraged to gradually increase their activity. Pain medications, including antiinflammatories, muscle relaxers, or in severe cases, **narcotics**, may be continued if needed.

Epidural steroid injections have been used to decrease pain by injecting an antiinflammatory drug, usually a corticosteroid, around the nerve root to reduce inflammation and **edema** (swelling). This partly relieves the pressure on the nerve root as well as resolves the inflammation.

Physical therapy

Physical therapists are skilled in treating acute back pain caused by the disk herniation. The physical therapist can provide noninvasive therapies, such as **ultrasound** or diathermy to project heat deep into the tissues of the back or administer manual therapy, if mobility of the spine is impaired. They may help improve posture and develop an **exercise** program for recovery and long-term protection. Appropriate exercise can help take pressure off inflamed nerve structures, while improving overall posture and flexibility. **Traction** can be used to try to decrease pressure on the disk. A lumbar support can be helpful for a herniated disk at this level as a temporary measure to reduce pain and improve posture.

Surgery

Surgery is often appropriate for conditions that do not improve with the usual treatment. In this event, a strong, flexible spine is important for a quick recovery after surgery. There are several surgical approaches to treating a herniated disk, including the classic discectomy, microdiscectomy, or percutaneous discectomy. The basic differences among these procedures are the size of the incision, how the disk is reached surgically, and how much of the disk is removed.

Discectomy is the surgical removal of the portion of the disk that is putting pressure on a nerve causing the back pain. In the classic disectomy, the surgeon first enters through the skin and then removes a bony portion of the vertebra called the lamina, hence the term **laminectomy**. The surgeon removes the disk material that is pressing on a nerve. Rarely is the entire lamina or disk entirely removed. Often, only one side is removed and the surgical procedure is termed hemilaminectomy.

In microdiscectomy, through the use of an operating microscope, the surgeon removes the offending bone or disk tissue until the nerve is free from compression or stretch. This procedure is possible using local **anesthesia**. **Microsurgery** techniques vary and have several advantages over the standard discectomy, such as a smaller incision, less **trauma** to the musculature and nerves, and easier identification of structures by viewing into the disk space through microscope magnification.

Percutaneous disk excision is performed on an outpatient basis, is less expensive than other surgical procedures, and does not require a general anesthesia. The purpose of percutaneous disk excision is to reduce the volume of the affected disk indirectly by

partial removal of the nucleus pulposus, leaving all the structures important to stability practically unaffected. In this procedure, large incisions are avoided by inserting devices that have cutting and suction capability. Suction is applied and the disk is sliced and aspirated.

Arthroscopic microdiscectomy is similar to percutaneous discectomy; however, it incorporates modified arthroscopic instruments, including scopes and suction devices. A suction irrigation of saline solution is established through two entry sites. A video discoscope is introduced from one site and the deflecting instruments from the opposite side. In this way, the surgeon is able to search and extract the nuclear fragments under direct visualization.

Laser disk decompression is performed using similar means as percutaneous excision and arthroscopic microdiscectomy, but laser energy is used to remove the disk tissue. Here, laser energy is percutaneously introduced through a needle to vaporize a small volume of nucleus pulposus, thereby dropping the pressure of the disk and decompressing the involved neural tissues. One disadvantage of this procedure is the high initial cost of the laser equipment. It is important to realize that only a very small percentage of people with herniated lumbar disks go on to require surgery. Further, surgery should be followed by appropriate **rehabilitation** to decrease the chance of reinjury.

Chemonucleolysis

Chemonucleolysis is an alternative to surgical excision. Chymopapain, a purified enzyme derived from the papaya plant, is injected percutaneously into the disk space to reduce the size of the herniated disks. It hydrolyses proteins, thereby decreasing water-binding capacity, when injected into the nucleus pulposus inner disk material. The reduction in size of the disk relieves pressure on the nerve root.

Spinal fusion

Spinal fusion is the process by which bone grafts harvested from the iliac crest (thick border of the ilium located on the pelvis) are placed between the intervertebral bodies after the disk material is removed. This approach is used when there is a need to reestablish the normal bony relationship between the vertebrae. A total discectomy may be needed in some cases because lumbar spinal fusion can help prevent recurrent lumbar disk herniation at a particular level.

Alternatives

Acupuncture involves the use of fine needles inserted along the pathway of the pain to move energy locally and relieve the pain. An acupuncturist determines the location of the nerves affected by the herniated disk and positions the needles appropriately. Massage therapists may also provide short-term relief from a herniated disk. Following manual examination and x-ray diagnosis, **chiropractic** treatment usually includes manipulation to correct muscle and joint malfunctions, while care is taken not to place an additional strain on the injured disk. If a full trial of conservative therapy fails, or if neurologic problems (weakness, bowel or bladder problems, and sensory loss) develop, the next step is usually evaluation by an orthopedic surgeon.

Prognosis

Only 5–10% of patients with unrelenting sciatica and neurological involvement, leading to chronic pain of the lumbar spine, need to have a surgical procedure performed. This strongly suggests that many patients with herniated disks at the lumbar level respond well to conservative treatment. For those patients who do require surgery for lumbar disk herniation, the reviewed procedures of nerve root decompression caused by disk herniation is favorable. Results of studies varied from 60–90% success rates. Disk surgery has progressively evolved in the direction of decreasing invasiveness. Each surgical procedure is not without possible complications, which can lead to chronic low back pain and restricted lifestyle.

Prevention

Proper exercises to strengthen the lower back and abdominal muscles are key in preventing excess **stress** and compressive forces on lumbar disks. Good posture will help prevent problems on cervical, thoracic, and lumbar disks. A good flexibility program is critical for prevention of muscle and spasm that can cause an increase in compressive forces on disks at any level. Proper lifting of heavy objects is important for all muscles and levels of the individual disks. Good posture in sitting, standing, and lying down is helpful for the spine. Losing weight, if needed, can prevent weakness and unnecessary stress on the disks caused by **obesity**. Choosing proper footwear may also be helpful to reduce the impact forces to the lumbar disks while walking on hard surfaces. Wearing special back support devices may be helpful if heavy lifting is required with combinations of twisting.

Hiatal hernia

Definition

A hiatal **hernia** is a condition in which a weakness or actual gap or tear in the large muscle of the diaphragm serves as an opening through which the stomach can enter the chest. Hiatal hernias can exist at birth (congenital hiatal hernia) or can develop later in life.

The diaphragm is a large dome-shaped sheet of muscle tissue that spans from the left to the right ribcage. It divides the chest area (thoracic cavity) from the abdominal cavity. The esophageal hiatus is the area of the diagphragm where the esophagus penetrates, joining the stomach below.

Along with other muscles of the abdomen and thoracic cavity, the diaphragm plays an important role in the process of respiration (breathing). During inspiration (breathing in), the muscle of the diaphragm contracts. This increases the volume of the thoracic cavity, and suction allows air to enter the lungs. During expiration, the diaphragm relaxes, and air is expelled from the lungs. The esophagus passes through an area of the diaphragm (the hiatus) on the way to the stomach, which helps prevent the backflow of stomach acid up the esophagus. The diaphragm plays a role in other functions, by virtue of its ability to increase pressure within the abdomen (intra-abdominal pressure)—in this capacity, it is crucial to the acts of **vomiting**, defecation, and urination.

Demographics

A hiatal hernia can occur due to an injury, or can develop over time due to some inherent weakness in the muscle fibers. Greatly increased intra-abdominal pressure, as may occur during **pregnancy**, can also induce a hiatal hernia. The following factors may contribute to the development of a hiatal hernia:

- obesity
- family history of hiatal hernia
- repeated straining due to constipation
- smoking
- heavy lifting
- chronic cough
- extreme bouts of violent vomiting
- age (about 60% of people develop some degree of hiatal hernia by the time they reach the age of 60)

Description

A hiatal hernia occurs when the stomach enters the chest cavity through a weakness or tear in the area of the diaphragm where the esophagus passes through. The most common form of hiatal hernia occurs when the gastroesophageal junction (the area where the esophagus enters the stomach) slides upward through the hernia opening. This is referred to as a sliding hiatal hernia. A rolling or paraesophageal hiatal hernia is much more rare. In this instance, the gastroesophageal junction does not protrude up into the thoracic cavity; instead, a portion of the stomach slides up alongside the esophagus, and protrudes into the chest cavity through the hiatal opening. This type of hiatal hernia is more dangerous, since there is a risk that the narrow confines through which the stomach protrudes will prevent proper blood circulation into this area of the stomach, causing its tissue to become oxygen deprived (strangulated).

While some people can have a hiatal hernia without any recognizable symptoms, other people have clear-cut discomfort related to the condition. Symptoms of a hiatal hernia are very similar to symptoms of gastric acid reflux, and include

- heartburn
- chest pain
- nausea
- frequent belching

Symptoms often get worse based on position (lying down, leaning forward) and activity (lifting heavy objects, straining for any reason). Over time, symptoms can worsen and cause coughing and asthma-like symptoms, **sore throat**, and swallowing problems (dysphagia). Anemia can develop when chronic acid reflux causes esophagitis with erosions of the esophagus or upper stomach.

Diagnosis/Preparations

Hiatal hernia is sometimes diagnosed when a chest x ray is performed for some other reason. In other instances, tests such as a barium swallow (upper GI series) or upper **endoscopy** may be performed specifically to look for the presence of a hiatal hernia.

Treatment

Treatment of a hiatal hernia often starts with treatment of the symptoms of gastroesophageal reflux that it induces, including medications such as **antacids**, **H-2 blockers**, and **proton pump inhibitors**. Practical recommendations include weight loss, stopping **smoking**, elevating the head of the bed at night, so that gravity discourages acid reflux, adjusting the diet to avoid **constipation** (and, therefore, straining at stool), and avoiding activities that cause straining (such as heavy lifting).

In some cases, surgical interventions will be required, particularly with very large hiatal hernias or with the rolling or paraesophageal form of hiatal hernia. Several surgical approaches may be utilized, all with the purpose of pulling the stomach back down into the abdomen, and decreasing the size of the hiatal opening. The surgery may be performed through an incision in the chest (thoracic access), abdomen (abdominal access), or using minimally invasive, laparoscopic techniques. Some of the surgeries used include Nissen fundoplication, Belsey (Mark IV) fundoplication, and Hill repair.

Hiccups

Definition

Hiccups are the result of an involuntary, spasmodic contraction of the diaphragm followed by the closing of the throat.

Demographics

A hiccup bout is an episode lasting more than a few minutes. If hiccups last longer than 48 hours, they are considered persistent or protracted. Hiccups lasting longer than one month are termed intractable. The longest recorded attack is six decades.

Hiccups can occur at any age and in utero. Preterm infants spend up to 2.5% of their time hiccupping. Although hiccups occur less frequently with age, intractable hiccups are more common in adult life. Females develop hiccups more frequently during early adulthood than males of the same age.

Hiccups are one of the most common, but mildest, disorders to which humans are prey. Virtually everyone experiences them at some point, but they rarely last long or require a doctor's care. Occasionally, a bout of hiccups will last longer than two days, earning it the name "persistent hiccups." Very few people will experience intractable hiccups, in which hiccups last longer than one month.

Description

A hiccup involves the coordinated action of the diaphragm and the muscles that close off the windpipe (trachea). The diaphragm is a dome-shaped muscle separating the chest and abdomen, normally responsible for expanding the chest cavity for inhalation. Sensation from the diaphragm travels to the spinal cord through the phrenic nerve and the vagus nerve, which pass through the chest cavity and the neck. Within the spinal cord, nerve fibers from the brain monitor sensory information and adjust the outgoing messages that control contraction. These messages travel along the phrenic nerve.

Irritation of any of the nerves involved in this loop can cause the diaphragm to undergo involuntary contraction, or spasm, pulling air into the lungs. When this occurs, it triggers a reflex in the throat muscles. Less than a tenth of a second afterward, the trachea is closed off, making the characteristic "hic" sound.

Causes and symptoms

Hiccups can be caused by central nervous system disorders, injury or irritation to the phrenic and vagus

WWW.BOOKBAZ.IR

nerves, and toxic or metabolic disorders affecting the central or peripheral nervous systems. They may be of unknown cause or may be a symptom of psychological **stress**. Hiccups often occur after drinking carbonated beverages or alcohol. They may also follow overeating or rapid temperature changes. Persistent or intractable hiccups may be caused by any condition that irritates or damages the relevant nerves, including:

- overstretching of the neck
- laryngitis
- heartburn (gastroesophageal reflux)
- irritation of the eardrum (which is innervated by the vagus nerve)
- general anesthesia
- surgery
- bloating
- tumor
- infection
- diabetes

Diagnosis

Hiccups are diagnosed by observation, and by hearing the characteristic sound. Diagnosing the cause of intractable hiccups may require imaging studies, blood tests, pH monitoring in the esophagus, and other tests.

Treatment

Most cases of hiccups will disappear on their own. Home remedies that interrupt or override the spasmodic nerve circuitry are often effective. Such remedies include:

- holding one's breath for as long as possible
- breathing into a paper bag
- swallowing a spoonful of sugar
- bending forward from the waist and drinking water from the wrong side of a glass

Treating any underlying disorder will usually cure the associated hiccups. Chlorpromazine (Thorazine) relieves intractable hiccups in 80% of cases. Metoclopramide (Reglan), carbamazepam, valproic acid (Depakene), and phenobarbital are also used. As a last resort, surgery to block the phrenic nerve may be performed, although it may lead to significant impairment of respiration.

Prognosis

Most cases of hiccups last no longer than several hours, with or without treatment.

Prevention

Some cases of hiccups can be avoided by drinking in moderation, avoiding very hot or very cold food, and avoiding cold showers. Carbonated beverages drunk through a straw deliver more gas to the stomach than when sipped from a container; therefore, avoid using straws.

High-density lipoproteins (HDL)

Definition

High-density lipoproteins (HDL) are molecules that are composed of fat (lipids) and protein. These lipoproteins transport **cholesterol**, which is a fat-like substance, around the human body. Cholesterol is present in all cells. Cholesterol-carrying HDL is called HDL cholesterol (HDL-C), and is sometimes known as "good" cholesterol. The amount of HDL-C in the bloodstream is part of a person's total cholesterol level. Medical professionals check a patient' cholesterol level as a means of monitoring their health. A low HDL reading has been linked to an increased risk of **heart disease**.

Description

Cholesterol cannot dissolve in the blood, and it is the job of the lipoproteins to transport cholesterol throughout the bloodstream. Lipoproteins also transport other molecules, including phospholipids (which contain

Activities to Increase HDL "Good" Cholesterol

Activity	Result
Live an active life	Regular activity boosts HDL.
Lose extra weight	Obesity is linked to low HDL.
Eat monounsaturated "good" fats	Olive oil, avocado, nuts, and cold-water fish seem to boost HDL.
Exercise first, eat fats later	Exercising on an empty stomach and eating monounsaturated fats afterwards seems to maximize the benefits of such foods.
Drink alcohol	Studies have shown that one alcoholic drink per day improves HDL levels.
Stop smoking	Smoking lowers HDL.
Avoid simple carbohydrates	Low HDL is linked to a diet high in simple carbohydrates even when paired with an active lifestyle.
Increase fiber intake	Daily fiber increases HDL.

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

phosphates) and **triglycerides** (fats found in the blood that mainly come from the food people eat).

Lipoproteins come in two major types: HDL and low-density lipoprotein (LDL). Both carry cholesterol, transporting it through the bloodstream. HDL cholesterol is often described as "good" cholesterol, and cholesterol-carrying LDL (LDL-C) is described as "bad." LDL can accumulate in the blood vessels and lead to atherosclerosis, which can clog arteries, and cause a **stroke** or a **heart attack**. HDL, on the other hand, removes LDL from the bloodstream and delivers it to the liver, where the LDL is broken down and eliminated. For that reason, a higher level of HDL-C has been considered to be a healthy reading, whereas a lower level of HDL-C might prompt a doctor to recommend measures to raise it.

Although it is widely accepted that higher levels of HDL promote cardiovascular health, a study in 2012 by Harvard School of Public Health researchers found that a subclass of HDL—a small protein known as apolipoprotein C-III (apoC-III) that sits on some HDL molecules—may actually heighten the risk of cardiovascular disease. The researchers noted that the identification of apoC-III is good news, as it will help guide future treatments that can target apoC-III while enhancing the healthy aspects of other forms of HDL.

In addition, a 2012 study published in the journal *Lancet* found that increasing HDL levels actually had no impact on a person's risk of heart disease. For this study, the researchers looked at people who had genes that confer naturally higher HDL levels throughout life, but found that they had no less incidence of heart disease than those who inherited genes that confer lower HDL levels, leading to the conclusion that HDL levels are not necessarily protective. Additional research is needed to clarify the role of HDL in disease risk.

Risk factors

A patient may experience a too-low level of HDL for many reasons. People who smoke or who are obese generally have lower levels of HDL. A person who is otherwise healthy may simply have a certain genetic makeup that causes his or her body to make less HDL.

Demographics

According to the National Health and Nutrition Examination Survey, nearly one in three men (31%) and one in eight women (12%) have low HDL levels. In both cases, the percentages decreased with age. For those age 60 and older, about 27% of men and 10 % of women have low HDL.

Causes and symptoms

The causes for low levels of HDL can be difficult to pinpoint. Some patients simply have a certain genetic makeup that directs their bodies to make a

WWW.BOOKBAZ.IR

low level of HDL. **Smoking** and **obesity** have been shown to increase the risk of low HDL levels. In addition, people who have certain genetic diseases, such as the rare Tangier disease or fish-eye disease, have a much reduced level of HDL, a condition known as hypoalphalipoproteinemia (HA).

Low HDL levels carry no symptoms, so unless patients have a cholesterol test, they will not know that they have reduced HDL.

Diagnosis

A blood test is used to reveal cholesterol level, which is measured in milligrams of cholesterol per deciliter of blood (mg/dL). To prepare for the test, patients are asked to fast for 12 hours and to refrain from smoking. Following the blood test, the sample is sent to a lab where HDL-C, LDL-C, and triglyceride levels are measured. The results are given as total blood cholesterol (a combination of HDL-C, LDL-C, and 20% of the triglyceride level), and typically also as the individual levels of each of the three components. An HDL-C level is considered optimal if it is 60 mg/dL or greater. An HDL level of lower than 40 mg/dL for men, or of lower than 50 mg/dL for women is considered low.

Treatment

If a patient's HDL level is low, the doctor may recommend one or more of the following lifestyle changes:

- quit smoking
- moderate consumption of alcoholic beverages, limiting consumption to no more than two drinks per day for men up to age 65, and to no more than one drink per day for men older than 65 and for women
- engage in regular aerobic exercise, preferably five sessions of 30 minutes per week, which has been shown to raise HDL levels by as much as 5%
- eat a healthy diet, reducing fat intake to no more than 25–35% of daily calorie total, and avoiding saturated and trans fats
- lose weight (for each 6 lb. (2.7 kg) lost, HDL may increase by 1 mg/dL).

Since HDL-C is just one component of an overall cholesterol reading, the doctor will look at HDL-C in conjunction with LDL-C and triglyceride levels before proceeding with treatment. In the past, doctors based treatment solely on the readings for total cholesterol and its constituents: They compared the patient's cholesterol-test numbers to guidelines that listed optimal or desired levels of each. If the patient's numbers fell outside those ranges, the physician would recommend lifestyle changes and/or treatments to achieve the desired levels. As of 2013, an expert panel of the American College of Cardiology (ACC) and American Heart Association (AHA) developed new guidelines in conjunction with the National Heart, Lung, and Blood Institute (NHLBI). Based on a review of randomized clinical trials, the panel found no evidence to support treatments to bring levels to a specific target, and eliminated the target numbers for the primary and secondary prevention of atherosclerotic cardiovascular disease. Instead, they provided recommendations regarding the appropriate intensity of statin therapy required in four groups of patients with differing characteristics, including LDL-C, but not HDL-C levels:

- for those with clinical atherosclerotic cardiovascular disease, use a high-intensity statin therapy (e.g., rosuvastatin) at 20–40 mg, or atorvastatin at 80 mg to achieve at least a 50% reduction in LDL-C levels
- for those with LDL-C levels of 190 mg/dL or greater, use a similar high-intensity statin therapy with the goal of achieving at least a 50% reduction in LDL-C levels
- for those who are 40–75 years old, have diabetes, and have LDL-C levels of 70–189 mg/dL (but no evidence of atherosclerotic cardiovascular disease), use a moderate-intensity statin (one that lowers LDL cholesterol by 30–49%), or possibly a high-intensity statin if the patient also has a 10-year, 7.5% or greater risk of atherosclerotic cardiovascular disease
- for those with LDL-C levels of 70–189 mg/dL and a 10-year, 7.5% or greater risk of atherosclerotic cardiovascular disease (but without evidence of cardiovascular disease or diabetes), use a moderate- or high-intensity statin

Prognosis

Many people with low HDL levels live long and healthy lives. Studies have shown a correlation between lower HDL levels and higher risk of cardiovascular disease. The connection is due to the fact that elevated levels of LDL can cause fat, cholesterol, and other substances to accumulate and form hard plaques that can narrow the blood vessels and also rupture. As a result, a patient may experience a heart attack or a stroke.

Prevention

A healthy lifestyle is the best preventive tactic for low HDL.

KEY TERMS

Atherosclerosis—Also known as "hardening of the arteries," atherosclerosis is characterized by the formation of plaques of in blood vessel walls, and is correlated with cardiovascular disease.

Cholesterol—A waxy, fat-like substance that occurs in all human body cells. It is important for making hormones, vitamin D, and other digestive substances.

Low-density lipoprotein (LDL)—A type of lipoprotein that transports cholesterol through the bloodstream. LDL cholesterol is known as "bad" because it can cause atherosclerosis, which is associated with cardiovascular disease.

Plaque—Hard collections of fatty materials that form in blood vessel walls.

Triglyceride—A type of fat found in the blood that is measured as part of a cholesterol blood test. High triglyceride levels are considered unhealthy.

High-risk pregnancy

Definition

A **pregnancy** that has maternal or fetal complications requiring special medical attention or bed rest is considered high-risk. Complications mean that the risk of illness or death before or after delivery is greater than normal for the mother or baby.

Demographics

According to the U.S. Centers for Disease Control and Prevention (CDC) there were 13.1 maternal deaths for every 100,000 live births in the United States in 2004. There was a large racial disparity in maternal deaths, with African American women experiencing 36.1 deaths per 100,00 live births in 2004 and white women experiencing 9.8 deaths per 100,000 live births the same year. The rate for Hispanic women was 8.5 per 100,000 live births. Over the past 100 years deaths due to pregnancy and **childbirth** have declined dramatically. In the early 1900s, giving birth was one of the most dangerous things a woman could do, with more than 600 women dying for every 100,000 live births in the year 1915.

Other statistics provide maternal mortality information by total female population, instead of per number of live births. In 2006, there were 115 deaths per 100,000 population due to pregnancy and childbirth among African American women, 70 deaths per 100,000 population among Hispanic and Latino women, 113 deaths per 100,000 population among white women, and 20 deaths per 100,000 population among Asian women. Common causes of death in women of childbearing age are problems related to pregnancy and delivery, including **blood clots** that travel to the lungs, **anesthesia** complications, bleeding, infection, and high blood pressure complications (pre-eclampsia and **eclampsia**).

A baby dies before, during, or shortly after birth in 16 out of 1,000 deliveries in the United States. Almost 50% of these deaths are stillbirths, which are sometimes unexplained. In 2005 there were 4.54 deaths in newborns before age 28 days per 1,000 live births, a total of 18,782 neonatal deaths. Risk factors for **stillbirth** and neonatal can be present before pregnancy occurs or develop during the course of the pregnancy.

Description

Risk factors in pregnancy are those findings discovered during prenatal assessment that are known to have a potentially negative effect on the outcome of the pregnancy, either for the woman or the fetus. This evaluation determines whether the mother has characteristics or conditions that make her or her baby more likely to become sick or die during the pregnancy.

The pregnant woman's interview at her first visit to the health care provider is conducted by the nurse, who obtains the data necessary to begin the high-risk screening. The physician or midwife caring for the pregnant woman will review the prenatal assessment sheet, order lab data, and obtain ultrasounds to determine if any risk factors are present. If it is determined that a woman has a high-risk pregnancy, she should be referred to a perinatologist for advanced care. This is the specialist who establishes and implements the medical regimen needed for the particular maternal/fetal complications likely to occur and the interdisciplinary team associated with the perinatal center works in its management. The perinatal team usually comprises a nutritionist, social worker, nurse educators, geneticists, ultrasonographers, and additional nursing staff who are responsible for the monitoring and supervising of ongoing team care of the patient.

Causes and symptoms

All risk factors do not threaten pregnancy to the same extent. The risk of complications is increased by **smoking**, poor nutritional habits, drug and alcohol abuse, domestic violence, prepregnancy maternal health status, psychosocial factors, prior health care, the presence of chronic medical problems in the mother, past history of repeated preterm delivery, multiple gestation, and abnormalities of the fetus or placenta. A woman with a high-risk pregnancy may have an earlier labor and delivery depending upon the fetal or maternal complication present and, likewise, present with symptoms dependent on the condition. Since the placenta supplies the baby with its nutrients and oxygen, any condition that threatens the blood supply to it threatens fetal development.

The threat of a preterm delivery is the most common reason for a referral to a perinatal center, which is linked to obstetric and newborn services that provide the highest level of care for a pregnant woman and her baby. A preterm delivery may occur because of a **premature rupture of membranes** (the bag of water surrounding the baby breaks) or preterm labor. There is a strong correlation of vaginal or uterine infection with the pregnant woman's water breaking, and there are laboratory tests that are predictive of a woman's risk of experiencing preterm labor.

Diagnosis

A risk-scoring sheet is used by many health care agencies during the prenatal assessment to establish if a woman may be at risk for complications during her pregnancy. This score sheet is implemented at the first prenatal visit, becomes a part of the woman's record, and is updated throughout the pregnancy as necessary. A woman's age affects pregnancy risk, as girls 15 years old and under are more likely to develop high blood pressure, protein in the urine and fluid accumulation, or seizures. They also are more likely to have underweight or undernourished babies. A woman 35 or older has a greater risk of developing high blood pressure or diabetes, as well as a much higher risk of having a chromosomal abnormality such as **Down syndrome**. A woman shorter than 5 ft. (1.5 m) or a woman weighing less than 100 lb. (45 kg) before pregnancy has a greater risk of having a small or preterm baby.

Laboratory data and **ultrasound** also are used to determine high-risk pregnancies by specific blood tests and imaging of the baby. A pregnancy may begin classified as low risk but be changed to a classification of high risk secondary to complications determined from the ongoing assessment of the pregnant woman. Since many of these complications can be managed with proper treatment, it is essential that a pregnant woman make and keep regular obstetric appointments.

Treatment

Treatment will vary, depending upon the maternal or fetal complication present. Generally, a woman with severe high-risk factors in pregnancy should be referred to a perinatal center to obtain the highest level of care for herself and her baby. Interventions to improve health status might include nutritional assessment; **physical examination**; teaching modalities for smoking cessation, drug and alcohol programs; prescribing medications related to the condition or changing pre-pregnancy medications (known to cause problems in the fetus); serial ultrasounds to learn fetal status; **amniocentesis**; fetal transfusions; **fetal surgery**; **antepartum testing**; bed rest; home health care; hospitalization; and early delivery. In a post-term pregnancy (greater than 42 weeks), the death of a baby is three times more likely than that of a normal term pregnancy (37–40 weeks). The treatment in this case would be to induce labor or perform a **cesarean section** before problems start to occur.

Prognosis

Advances in the management of complications in high-risk pregnancies have provided women with a means of controlling their risks, which substantially increases the potential for a successful outcome. Since it is impossible to guarantee a good outcome in a normal pregnancy, it is even more difficult to ensure that a high-risk pregnancy will result in a healthy infant and mother. A woman who strictly adheres to the medical regimen established for her will greatly increase her chances of a positive result.

Prevention

The early weeks of pregnancy are the most crucial ones for the fetus. Many women do not know they are pregnant until several weeks after conception, so education about the need for preconceptional care is essential. Preconception counseling guides a woman in planning a healthy pregnancy. These are some of the factors to which attention must be paid:

- family history
- medical history
- past pregnancies
- current medications
- lifestyle
- environment
- infections

The number one preventable cause of intellectual disabilities (ID) in infants is alcohol use during pregnancy. Alcohol can cause problems ranging from **miscarriage** to severe behavioral problems in the baby or developing child even if no obvious physical **birth defects** are apparent. **Fetal alcohol syndrome** is seen in about 2 out of 1,000 live births.

Cigarette smoking is the most common **addiction** among pregnant women in the United States, and despite the health hazards of smoking being well known, only about 20% of these women actually quit during pregnancy. One risk of smoking during pregnancy is having a baby who may die from **sudden infant death syndrome** (SIDS).

Drugs known to cause birth defects when taken during pregnancy include: alcohol, dilantin (phenytoin), any drug that interferes with the actions of **folic acid**, lithium, streptomycin, tetracycline, thalidomide, warfarin (Coumadin), and isotretinoin (Accutane), which is prescribed for **acne**.

Infections that may cause birth defects include: herpes simplex, viral hepatitis, the flu, **mumps**, German **measles** (**rubella**), **chickenpox** (varicella), **syphilis**,

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—A procedure that uses ultrasound to guide a needle into the amniotic sac (bag of waters) surrounding the baby and obtain fluid to analyze for genetic abnormalities.

Antepartum—The time period of the woman's pregnancy from conception and onset of labor.

Down syndrome—The most prevalent of a class of genetic defects known as trisomies, in which cells contain three copies of certain chromosomes rather than the usual two. Down syndrome, or trisomy 21, usually results from three copies of chromosome 21.

Perinatal—The time period shortly before and after birth, generally from around the 20th week of pregnancy to one to four weeks after birth.

Perinatologist—A specialist in the branch of obstetrics that deals with the high-risk pregnant woman and her fetus.

Preconceptional—The time period before pregnancy (conception) occurs.

Ultrasonographer—The person who performs the radiologic technique of ultrasound in which deep structures of the body are visualized.

toxoplasmosis (occurs from eating undercooked meat and handling kitty litter), **listeriosis**, and infections from the coxsackievirus or cytomegalovirus (CMV). Many adults have been exposed to coxsackievirus and CMV when they were younger, but many have not. Those who have not been exposed should pay careful attention to any illnesses they have early in their pregnancy, noting the onset, presence of **fever**, muscle aches and pains, and duration of illness to report to their physician.

Hemolytic disease of the newborn (destruction of the red blood cells) can occur when Rh incompatibility exists between child and mother. The most common cause of incompatible blood types is Rh incompatibility, such as when the mother has Rh-negative blood and the father has Rh-positive blood. The baby may have Rh-positive blood, in which case the mother's body produces antibodies against the baby's blood. The mother can be treated with Rhogham [Rh0(D)immune globulin], which can be given to the mother in the first 72 hours after delivery and at the twenty-eighth week of pregnancy; it will destroy any antibodies produced by her blood and significantly decrease the risk associated with pregnancies with Rh-factor incompatibilities.

There are other incompatible blood factors during the prenatal assessment period that can cause anemia in the fetus and require ongoing monitoring. Many women are frequently deficient in folic acid, a B vitamin used in the synthesis of ribonucleic acid (RNA) and essential, in large quantities, for optimal protein synthesis in the fetus. This is especially true in the early weeks of pregnancy, when all cell division and organ development is occurring. Thus, the best prevention for a high risk pregnancy is good planning.

Hip replacement

Definition

Hip replacement is a procedure in which the surgeon removes damaged or diseased parts of the patient's hip joint and replaces them with new artificial parts. The operation itself is called hip **arthroplasty**. Arthroplasty comes from two Greek words, *arthros*, or joint, and *plassein*, "to form or shape." It is a type of surgery done to replace or reconstruct a joint. The artificial joint itself is called a prosthesis. Hip prostheses may be made of metal, ceramic, plastic, or various combinations of these materials.

Purpose

Hip arthroplasty has two primary purposes: **pain** relief and improved functioning of the hip joint.

The components of a prosthetic hip joint, removed due to loosening. On the right is the metal shaft encased in the cement which fixed it to the inside of the femur. On the left is the plastic socket. *(Custom Medical Stock Photo, Inc.)*

Pain relief

Because total hip replacement (THR) is considered major surgery, with all the usual risks involved, it is usually not considered as a treatment option until the patient's pain cannot be managed any longer by more conservative nonsurgical treatment.

Joint pain interferes with a person's quality of life in many ways. If the pain in the hip area is chronic, affecting the person even when he or she is resting, it can lead to depression and other emotional disturbances. Severe chronic pain also strains a person's relationships with family members, employer, and workplace colleagues; it is now recognized to be the most common underlying cause of **suicide** in the United States.

In most cases, pain in the hip joint is a gradual development. Typically, the patient finds that their hip begins to ache when they are exercising vigorously, walking, or standing for a long time. They may cut back on athletic activities only to find that they are starting to limp when they walk and that sitting down is also becoming uncomfortable. Many patients then begin to have trouble driving, sitting through a concert or movie, or working at a desk without pain. It is usually at this point, when a person's ability to live independently is threatened, that he or she considers hip replacement surgery.

Joint function

Restoration of joint function is the other major purpose of hip replacement surgery. The hip joint is one of the most active joints in the human body, designed for many different types of movement. It consists of the head (top) of the femur (thighbone), which is shaped like a ball, and a part of the pelvic bone called the acetabulum, which looks like a hollow or socket. In a healthy hip joint, a layer of cartilage lies between the head of the femur and the acetabulum. The cartilage keeps the bony surfaces from grinding against each other, and allows the head of the femur to rotate or swivel in different directions inside the socket formed by the acetabulum. It is this range of motion, as well as the hip's ability to support the weight of the upper body, that is gradually lost when the hip joint deteriorates. The prostheses used in hip replacement surgery are intended to restore as much of the functioning of the hip joint as possible. The level of function in the hip after the surgery depends in part on the reason for the damage to the joint.

Disorders and conditions that may lead to the need for hip replacement surgery include:

- Osteoarthritis (OA). Osteoarthritis is a disorder in which the cartilage in the joints of the body gradually

WWW.BOOKBAZ.IR

A false color x-ray image of the human pelvis showing a prosthetic hip joint. *(Custom Medical Stock Photo, Inc.)*

breaks down, allowing the surfaces of the bones to rub directly and wear against each other. Eventually the patient experiences swelling, pain, inflammation, and increasing loss of mobility. OA most often affects adults over age 45, and is thought to result from a combination of wear and tear on the joint, lifestyle, and genetic factors. OA is the most common cause of joint damage requiring hip replacement.

- Rheumatoid arthritis (RA). Rheumatoid arthritis is a disease that begins earlier in life than OA and affects the whole body. Women are three times as likely as men to develop RA. Its symptoms are caused by the immune system's attacks on the body's own cells and tissues. Patients with RA often suffer intense pain even when they are not putting weight on the affected joints.
- Trauma. Damage to the hip joint from a fall, automobile accident, or workplace or athletic injury may trigger the process of cartilage breakdown in the hip joint.
- Avascular necrosis. Avascular necrosis, which is also called osteonecrosis, is a disorder caused by the loss of blood supply to bone tissue. Bone starved for blood supply becomes weak and eventually collapses. The most common reasons for loss of blood supply include trauma, the use of steroid medications, certain blood disorders, and alcoholism. Avascular necrosis often affects the top of the femur that forms part of the hip joint. It develops most frequently in adults between the ages of 30 and 50.
- Ankylosing spondylitis (AS). Ankylosing spondylitis is a less common form of arthritis that primarily affects the bones in the spine and pelvis. These bones gradually fuse together when the body replaces inflamed tendons or ligaments with new bone instead of elastic connective tissue. AS typically develops in the patient's late teens or early twenties, with three times as many men affected as women.

Demographics

About 320,000 hip replacement operations are performed in the United States each year, most of them in patients over the age of 60. According to the American Academy of Orthopaedic Surgeons (AAOS), only 5–10% of total hip replacements were in patients younger than 50. There are two reasons for this concentration in older adults. Arthritis and other degenerative joint disorders are the most common health problems requiring hip replacement, and they become more severe as people grow older. The second reason is the limited life expectancy of the prostheses used in hip replacements. Because THR is a complex procedure and requires a long period of recovery after surgery, doctors generally advise patients to put off the operation as long as possible so that they will not need to undergo a second operation later to insert a new prosthesis.

This demographic picture is changing rapidly because of advances in designing hip prostheses, as well as changes in older Americans' rising expectations of quality of life. Many people are less willing to tolerate years of pain or limited activity in order to postpone surgery. In addition, hip prostheses are lasting longer than those used in the 1960s; one study found that 65% of the prostheses in patients who had THR before the age of 50 were still intact and functioning well 25 years after the surgery. A larger number of hip replacements are now being done in younger patients, and the operation itself is being performed more often.

Description

Hip replacement surgery is a relatively recent procedure that had to wait for the invention of plastics

and other synthetic materials to make reliable prostheses that could withstand years of wear. The first successful total hip replacement was performed in 1962 by Sir John Charnley (1911–1982), a British orthopedic surgeon who designed a device that is still known as a Charnley prosthesis. Charnley used a stainless steel ball mounted on a stem that was inserted into the patient's thighbone to replace the femoral head. A high-density polyethylene socket was fitted into the acetabular side of the joint. Both parts of the Charnley prosthesis were secured to their respective sides of the joint with acrylic polymer cement. More recent developments include the use of cobalt chrome alloys or ceramic materials in place of stainless steel, as well as methods for holding the prosthesis in place without cement.

There are three major types of hip replacement surgery performed in the United States: a standard procedure for hip replacement; a newer technique known as **minimally invasive surgery** (MIS), pioneered in Chicago in February 2001; and revision surgery, which is done to replace a loosened or damaged prosthesis.

Standard hip replacement surgery

A standard hip replacement operation takes 1.5–3 hours. The patient may be given a choice of general, spinal, or epidural **anesthesia**. An epidural anesthesia, which is injected into the space around the spinal cord to block sensation in the lower body, causes less blood loss and also lowers the risk of **blood clots** or breathing problems after surgery. After the patient is anesthetized, the surgeon makes an incision 8–12 in. (20–30 cm) long down the side of the patient's upper thigh. The surgeon may then choose to enter the joint itself from the side, back, or front. The back approach is the most common. The ligaments and muscles under the skin are then separated.

Once inside the joint, the surgeon separates the head of the femur from the acetabulum and removes the head with a saw. The surgeon uses a power drill and a special reamer to remove the cartilage from the acetabulum and shape it to accept the acetabular part of the prosthesis. This part of the new prosthesis is a curved piece of metal lined with plastic or ceramic.

After selecting the correct size for the patient, the surgeon inserts the acetabular component. If the new joint is to be cemented, the surgeon will attach the component to the bone with a type of epoxy. Otherwise, the metal plate will be held in place by screws or by the tightness of the fit itself.

To replace the femoral head, the surgeon first drills a hole inside the thighbone to accept a stem for the femoral component. The stem may be cemented in place or held in place by the tightness of the fit. A metal or ceramic ball to replace the head of the femur is then attached to the stem.

After the prosthesis is in place, an x ray is taken to verify that it is correctly positioned. The incision is then washed with saline solution as a safeguard against infection. The sutures used to close the deeper layers of tissue are made of a material that the body eventually absorbs, while the uppermost layer of skin is closed with metal surgical staples. The staples are removed 10–14 days after surgery.

Finally, a large triangular pillow known as a Charnley pillow is placed between the patient's ankles to prevent dislocation of the hip during the first few days after surgery.

Minimally invasive hip replacement surgery

Minimally invasive surgery (MIS) is a newer technique of hip replacement, introduced in 2001. Instead of making one long incision, the surgeon uses two 2 in. (5 cm) incisions or one 3.5 in. (9 cm) incision. Using newly designed smaller implements, the surgeon removes the damaged bone and inserts the parts of the new prosthesis. MIS hip replacement takes only an hour and a half. As there is less bleeding, the patient can leave the hospital the next day. Obese patients or those with very weak bones are not considered for MIS.

Revision surgery

Revision surgery is most commonly performed to replace a prosthesis that no longer fits or functions well because the bone in which it is implanted has deteriorated with age or disease. Revision surgery is a much more complicated process than first-time hip replacement; it sometimes requires a specialized prosthesis as well as bone grafts from the patient's pelvis, and its results are not usually as good. However, some patients have had as many as three revision operations with satisfactory results.

Diagnosis

Because pain in the hip joint is usually a gradual development, its cause has been diagnosed in most cases by the time the patient is ready to consider hip replacement surgery. The doctor will have taken a careful medical and employment history in order to determine the most likely cause of the pain and whether the patient's job may be a factor. The doctor

WWW.BOOKBAZ.IR

will also ask about a family history of **osteoarthritis** as well as other disorders known to run in families. The patient will be asked about injuries, falls, or other accidents that may have affected the hip joint, and about his or her use of alcohol and prescription medications—particularly **steroids**, which can cause avascular **necrosis**. The doctor will also order an x ray of the affected hip to show the location and extent of damage to the hip joint.

Other diagnostic tests that may be ordered include:

- Aspiration. Aspiration is a procedure in which fluid is withdrawn from the joint by a needle and sent to a laboratory for analysis. It is done to check for infection in the joint.
- Arthrogram. An arthrogram is a special type of x ray in which a contrast dye is injected into the hip to outline the cavity surrounding the joint.
- Magnetic resonance imaging (MRI). An MRI uses a large magnet, radio waves, and a computer to generate images of the head and back. It is helpful in diagnosing avascular necrosis.
- Computed axial tomography (CAT) scan. A CAT scan is another specialized type of x ray that uses computers to generate three-dimensional images of the hip joint. It is most often used to evaluate the severity of avascular necrosis and to obtain a more accurate picture of malformed or unusually shaped joints.
- Bone densitometry test. This test measures the density or strength of the patient's bones. It does not require injections; the patient lies flat on a padded table while an imager passes overhead. This test is most often given to patients at risk for osteoporosis or other disorders that affect bone density.

Precautions

To evaluate his or her fitness for surgery, the patient will be given a complete **physical examination**. Certain disorders, including Parkinson's disease, **dementia** and other conditions of altered mental status, **kidney disease**, advanced **osteoporosis**, disorders associated with muscle weakness, diabetes, and an unstable cardiovascular system are generally considered contraindications to hip replacement surgery. People with weakened immune systems may also be advised against surgery. In the case of **obesity**, the operation may be postponed until the patient loses weight. The stress placed on the hip joint during normal walking can be as high as three times the patient's body weight; thus, each pound (0.5 kg) in weight reduction equals 3 lb. (1.4 kg) in **stress reduction**. Consequently, weight reduction lowers an obese patient's risk of complications after the operation.

Preparation

Hip replacement surgery requires extensive and detailed preparation on the patient's part because it affects so many aspects of life.

Legal and financial considerations

In the United States, physicians and hospitals are required to verify the patient's insurance benefits before surgery and to obtain pre-certification from the patient's insurer or from Medicare. Without health insurance, the total cost of a hip replacement can run tens of thousands of dollars. In addition to insurance documentation, patients are legally required to sign an informed consent form prior to surgery to signify that the patient is a knowledgeable participant in making healthcare decisions. The doctor will discuss all of the following with the patient before he or she signs the form: the nature of the surgery; reasonable alternatives to the surgery; and the risks, benefits, and uncertainties of each option. Informed consent also requires the doctor to make sure that the patient understands the information that has been given.

Medical considerations

Patients are asked to do the following in preparation for hip replacement surgery:

- Get in shape physically by doing exercises for strengthening the heart and lungs, building up the muscles around the hip, and increasing the range of motion of the hip joint. Many clinics and hospitals distribute illustrated pamphlets of pre-operation exercises.
- Lose weight if the surgeon recommends it.
- Quit smoking, as smoking weakens the cardiovascular system and increases the risks that the patient will have breathing difficulties under anesthesia.
- Make donations of one's own blood for storage in case a transfusion is necessary during surgery. This procedure is known as autologous blood donation; it has the advantage of avoiding the risk of transfusion reactions or transmission of diseases from infected blood donors.
- Have necessary dental work completed before the operation. This precaution is necessary because small numbers of bacteria enter the bloodstream whenever a dentist performs any procedure that causes the gums to bleed. Bacteria from the mouth can be carried to the site of the hip replacement and cause an infection.
- Discontinue taking birth control pills and any anti-inflammatory medications (aspirin or NSAIDs) two

weeks before surgery. Most doctors also recommend discontinuing any alternative herbal preparations at this time, as some of them interact with anesthetics and pain medications.

Lifestyle changes

Hip replacement surgery requires a long period of recovery at home after leaving the hospital. Since the patient's physical mobility will be limited, he or she should do the following before the operation:

- Arrange for leave from work, help at home, help with driving, and similar tasks and commitments.
- Obtain a handicapped parking permit.
- Check the living quarters thoroughly for needed adjustments to furniture, appliances, lighting, and personal conveniences. People recovering from hip replacement surgery must minimize bending, stooping, and any risk of falling.
- Stock up on nonperishable groceries, cleaning supplies, and similar items in order to minimize the need for shopping.
- Have a supply of easy-care clothing with elastic waistbands and simple fasteners in front rather than complicated ties or buttons in the back. Shoes should be slip-ons or fastened with Velcro.

Many hospitals and clinics now have classes for patients scheduled for hip replacement surgery. These classes answer questions regarding preparation for the operation and what to expect during recovery, but in addition they provide opportunities for patients to share concerns and experiences. Studies indicate that patients who have attended these pre-operation classes are less anxious before surgery and generally recover more rapidly.

Aftercare

Aftercare following hip replacement surgery begins while the patient is still in the hospital. Most patients will remain there for 5–10 days after the operation. During this period, the patient will be given fluids and antibiotic medications intravenously to prevent infection. Medications for pain will be given every 3–4 hours, or through a device known as a PCA (patient-controlled anesthesia), which is a small pump that delivers a dose of medication into the IV when the patient pushes a button. To get the lungs back to normal functioning, a respiratory therapist will ask the patient to **cough** several times a day or breathe into blow bottles.

Aftercare during the hospital stay is also intended to lower the risk of a venous thromboembolism (VTE), or blood clot in the deep veins of the leg. Prevention of VTE involves medications to thin the blood; exercises for the feet and ankles while lying in bed; and wearing thromboembolic deterrent (TED) or **deep vein thrombosis** (DVT) stockings. TED stockings are made of nylon (usually white) and may be knee-length or thigh-length; they help to reduce the risk of a blood clot forming in the leg vein by putting mild pressure on the veins. TED stockings are worn for 2–6 weeks after surgery.

Physical therapy is also begun during the patient's hospital stay, often on the second day after the operation. The physical therapist will introduce the patient to using a walker or crutches and explain how to manage such activities as getting out of bed or showering without dislocating the new prosthesis. In addition to increasing the patient's level of physical activity each day, the physical therapist will help the patient select special equipment for recovery at home. Commonly recommended devices include a reacher for picking up objects without bending too far, a sock cone and special shoehorn, and bathing equipment.

Following **discharge from the hospital**, the patient may go to a skilled nursing facility, **rehabilitation** center, or directly home. Ongoing physical therapy is the most important part of recovery for the first 4–5 months following surgery. Most insurance companies in the United States allow home visits by a home health aide, visiting nurse, and physical therapist for 3–4 weeks after surgery. The physical therapist will monitor the patient's progress as well as suggest specific exercises to improve strength and range of motion. After the home visits, the patient is encouraged to take up other forms of physical activity in addition to the exercises; swimming, walking, and pedaling a stationary bicycle are all good ways to speed recovery. The patient may take a mild medication for pain (usually **aspirin** or ibuprofen) 30–45 minutes before an **exercise** session, if needed.

Most patients can start driving 6–8 weeks after the operation and return to work full time after 8–10 weeks, depending on the amount and type of physical exertion their jobs require. Some patients arrange to work on a part-time basis until their normal level of energy returns.

Risks

Hip replacement surgery involves both short- and long-term risks.

WWW.BOOKBAZ.IR

Short-term risks

The most common risks associated with hip replacement are as follows:

- Dislocation of the new prosthesis. Dislocation is most likely to occur in the first 10–12 weeks after surgery. It is a risk because the ball and socket in the prosthesis are smaller than the parts of the natural joint, and can move out of place if the patient places the hip in certain positions. The three major rules for avoiding dislocation are: do not cross the legs when lying, sitting, or standing; never lean forward past a 90° angle at the waist; and do not roll the legs inward toward each other—keep the feet pointed forward or turned slightly outward.
- Deep vein thrombosis (DVT). There is some risk (about 1.5% in the United States) of a clot developing in the deep vein of the leg after hip replacement surgery because the blood supply to the leg is cut off by a tourniquet during the operation. The blood-thinning medications and TED stockings used after surgery are intended to minimize the risk of DVT.
- Infection. The risk of infection is minimized by storing autologous blood for transfusion and administering intravenous antibiotics after surgery. Infections occur in fewer than 1% of hip replacement operations.
- Injury to the nerves that govern sensation in the leg. This problem usually resolves over time.

Long-term risks

The long-term risks of hip replacement surgery include:

- Inflammation related to wear and tear on the prosthesis. Tiny particles of debris from the prosthesis can cause inflammation in the hip joint and lead to dissolution and loss of bone. This condition is known as osteolysis.
- Heterotopic bone. Heterotopic bone is bone that develops in the space between the femur and the pelvis after hip replacement surgery. It can cause stiffness and pain, and may have to be removed surgically. The cause is not completely understood, but is thought to be a reaction to the trauma of the operation. In the United States, patients are usually given indomethacin (Indocin) to prevent this process; in Germany, surgeons are using postoperative radiation treatments together with Indocin.
- Changed length of leg. Some patients find that the operated leg remains slightly longer than the other leg even after recovery. This problem does not interfere with mobility and can usually be helped by an orthotic shoe insert.
- Loosening or damage to the prosthesis itself. This development is treated with revision surgery.

Results

Normal results are relief of chronic pain, greater ease of movement, and much improved quality of life. Specific areas of improvement depend on a number of factors, including the patient's age, weight, and previous level of activity; the disease or disorder that caused the pain; the type of prosthesis; and the patient's attitude toward recovery. In general, total hip replacement is considered one of the most successful procedures in modern surgery.

It is difficult to estimate the "normal" lifespan of a hip prosthesis. The figure quoted by many surgeons—between 10 and 15 years—is based on statistics from the early 1990s. It is too soon to tell how much longer the newer prostheses will last. In addition, as hip replacements become more common, the increased size of the worldwide patient database will allow for more accurate predictions. It is known that younger patients and obese patients wear out hip prostheses more rapidly.

Morbidity and mortality rates

Information about mortality and complication rates following THR is limited because the procedure is considered elective. The most important factor affecting morbidity and mortality rates in the United States, according to a Harvard study, is the volume of THRs performed at a given hospital or by a specific surgeon: the higher the volume, the better the outcomes.

Alternatives

Nonsurgical alternatives

The most common conservative alternatives to hip replacement surgery are assistive devices (canes or walkers) to reduce stress on the affected hip; exercise regimens to maintain joint flexibility; dietary changes, particularly if the patient is overweight; and **analgesics**, or painkilling medications. Most patients who try medication begin with an over-the-counter NSAID such as ibuprofen (Advil). If the pain cannot be controlled by nonprescription analgesics, the doctor may give the patient cortisone injections, which relieve the pain of arthritis by reducing inflammation. Unfortunately, the relief provided by cortisone tends to diminish with each injection; moreover, the drug can produce serious side effects.

KEY TERMS

Acetabulum—The socket-shaped part of the pelvis that forms part of the hip joint.

Analgesic—A medication given to relieve pain.

Ankylosing spondylitis—A form of inflammatory arthritis in which the bones in the spine and pelvis gradually fuse when inflamed connective tissue is replaced by bone.

Arthrodesis—A surgical procedure sometimes used to treat younger patients with hip problems, in which the head of the femur is fused directly to the acetabulum.

Arthroplasty—Surgical replacement of a joint. Arthroplasty can refer to knee as well as hip replacement.

Autologous blood—The patient's own blood is drawn and set aside for use during surgery in case a transfusion is needed.

Avascular necrosis—A disorder in which bone tissue dies and collapses following the temporary or permanent loss of its blood supply; it is also known as osteonecrosis.

Cartilage—A whitish elastic connective tissue that allows the bones forming the hip joint to move smoothly against each other.

Cortisone—A steroid compound used to treat autoimmune diseases and inflammatory conditions. It is sometimes injected into a joint to relieve the pain of arthritis.

Deep venous thrombosis (DVT)—The formation of a blood clot in the deep vein of the leg. It is considered a serious complication of hip replacement surgery.

Epidural—A method of administering anesthesia by injecting it into the lower spine in the space around the spinal cord. Epidural anesthesia blocks sensation in the parts of the body below the level of the injection.

Femur—The medical name for the thighbone.

Heterotopic bone—Bone that develops as an excess growth around the hip joint following surgery.

Nonsteroidal anti-inflammatory drugs (NSAIDs)—A term used for a group of analgesics that also reduce inflammation when used over a period of time. NSAIDs are often given to patients with osteoarthritis.

Orthopaedics—The branch of surgery that treats deformities or disorders affecting the musculoskeletal system.

Osteolysis—Dissolution and loss of bone resulting from inflammation caused by particles of debris from a prosthesis.

Osteotomy—A surgical alternative to a hip prosthesis, in which the surgeon cuts through the pelvis or femur in order to realign the hip.

Prosthesis (plural, prostheses)—An artificial device that substitutes for or supplements a missing or damaged body part. Prostheses may be either external or implanted inside the body.

Tourniquet—A tube or pressure cuff that is tightened around a limb in order to compress a vein to stop bleeding.

Complementary and alternative (CAM) approaches

Complementary and alternative forms of therapy cannot be used as substitutes for hip replacement surgery, but they are helpful in managing pain before and after the operation, and in speeding physical recovery. Many patients also find that CAM therapies help them maintain a positive mental attitude in coping with the emotional stress of surgery and physical therapy. CAM therapies that have been shown to relieve the pain of rheumatoid and osteoarthritis include **acupuncture**, **music therapy**, naturopathic treatment, homeopathy, **Ayurvedic medicine**, and certain herbal preparations. Chronic pain from other disorders affecting the hip has been successfully treated with **biofeedback**, relaxation techniques, **chiropractic** manipulation, and mindfulness **meditation**.

Some types of **movement therapy** are recommended in order to postpone the need for hip surgery. **Yoga**, tai chi, **qigong**, and dance therapy help to maintain strength and flexibility in the hip joint, and to slow down the deterioration of cartilage and muscle tissue. Exercise in general has been shown to reduce a person's risk of developing osteoporosis.

Alternative surgical procedures

Other surgical options include:

- Osteotomy. An osteotomy is a procedure in which the surgeon cuts the thigh bone or pelvis in order to realign the hip. It is done more frequently in Europe than in the United States, but it has the advantage of not requiring artificial materials.

WWW.BOOKBAZ.IR

- Arthrodesis. This type of operation is rarely performed except in younger patients with injury to one hip. In this procedure, the head of the femur is fused to the acetabulum with a plate and screws. The major advantage of arthrodesis is that it places fewer restrictions on the patient's activity level than a hip replacement.
- Pseudarthrosis. In this procedure, the head of the femur is removed without any replacement, resulting in a shorter leg on the affected side. It is usually performed when the patient's bones are too weak for implanting a prosthesis or when the hip joint is badly infected. This procedure is sometimes called a Girdlestone operation, after the surgeon who first used it in the 1940s.

Health care team roles

Hip replacement surgery is performed by an orthopedic surgeon, who has received advanced training in surgical treatment of disorders of the musculoskeletal system. Qualification for this specialty in the United States requires a minimum of five years of training after medical school. Most orthopedic surgeons who perform joint replacements have had additional specialized training in these specific procedures. If surgery is being considered, it is a good idea to find out how many hip replacements the surgeon performs each year; those who perform 200 or more have had more opportunities to refine their technique.

Hip replacement surgery can be performed in a hospital with a department of **orthopedic surgery**, but is also performed in specialized clinics or institutes for joint disorders. MIS is performed in a small number of specialized facilities and teaching hospitals attached to major university medical schools.

Rebecca Frey, PhD
REVISED BY ROSALYN CARSON-DEWITT, MD

Hirschsprung's disease

Definition

Hirschsprung's disease, also known as congenital megacolon or aganglionic megacolon, is an abnormality in which certain nerve fibers are absent in segments

of the bowel, resulting in severe bowel obstruction. It was first identified in 1886 by a physician named Harold Hirschsprung.

Description

Hirschsprung's disease is caused when certain nerve cells (called parasympathetic **ganglion** cells) in the wall of the large intestine (colon) do not develop before birth. Without these nerves, the affected segment of the colon lacks the ability to relax and move bowel contents along. This causes a constriction and as a result, the bowel above the constricted area dilates due to stool becoming trapped, producing megacolon (dilation of the colon). The disease can affect varying lengths of bowel segment, most often involving the region around the rectum. In up to 10% of children the entire colon and part of the small intestine are involved. This condition is known as total colonic aganglionosis, or TCA.

Hirschprung's disease occurs once in every 5,000 live births, and it is about four times more common in males than females. Between 4% and 50% of siblings are also afflicted. The wide range for recurrence is due to the fact that the recurrence risk depends on the gender of the affected individual in the family (i.e., if a female is affected, the recurrence risk is higher) and the length of the aganglionic segment of the colon (i.e., the longer the segment that is affected, the higher the recurrence risk).

Causes and symptoms

Hirschsprung's disease occurs early in fetal development when, for unknown reasons, there is either failure of nerve cell development, failure of nerve cell migration, or arrest in nerve cell development in a segment of the bowel. The absence of these nerve fibers, which help control the movement of bowel contents, is what results in intestinal obstruction accompanied by other symptoms.

There is a genetic basis to Hirschsprung's disease, and it is believed that it may be caused by different genetic factors in different subsets of families. Proof that genetic factors contribute to Hirschprung's disease is that it is known to run in families, and it has been seen in association with some chromosome abnormalities. For example, about 10% of children with the disease have **Down syndrome** (the most common chromosomal abnormality). Molecular diagnostic techniques have identified many genes that cause susceptibility to Hirschprung's disease. As of 2014, a total of six genes have been identified: the RET gene, the glial cell line-derived neurotrophic factor gene, the endothelin-B receptor gene, endothelin converting enzyme, the endothelin-3 gene, and the Sry-related transcription factor SOX10. Mutations that inactivate the RET gene are the most frequent, occurring in 50% of familial cases (cases that run in families) and 15–20% of sporadic (non-familial) cases. Mutations in these genes do not cause the disease, but they make the chance of developing it more likely. Mutations in other genes or environmental factors are required to develop the disease, and these other factors are not understood. At least three chromosomes are known to be involved: 13q22, 21q22, and 10q. Hirschsprung's disease has also been reported in association with abnormal forms of chromosome 18.

For persons with a ganglion growth beyond the sigmoid segment of the colon, the inheritance pattern is autosomal dominant with reduced penetrance (risk closer to 50%). For persons with smaller segments involved, the inheritance pattern is multifactorial (caused by an interaction of more than one gene and environmental factors, risk lower than 50%) or autosomal recessive (one disease gene inherited from each parent, risk closer to 25%) with low penetrance.

The initial symptom is usually severe, continuous **constipation**. A newborn may fail to pass meconium (the first stool) within 24 hours of birth, may repeatedly vomit yellow- or green-colored bile and may have a distended (swollen, uncomfortable) abdomen. Occasionally, infants may have only mild or intermittent constipation, often with **diarrhea**.

While two-thirds of cases are diagnosed in the first three months of life, Hirschsprung's disease may also be diagnosed later in infancy or childhood. Occasionally, even adults are diagnosed with a variation of the disease. In older infants, symptoms and signs may include anorexia (lack of appetite or inability to eat), lack of the urge to move the bowels or empty the rectum on **physical examination**, distended abdomen, and a mass in the colon that can be felt by the physician during examination. It should be suspected in older children with abnormal bowel habits, especially a history of constipation dating back to infancy and ribbon-like stools.

Occasionally, the presenting symptom may be a severe intestinal infection called enterocolitis, which is life-threatening. The symptoms are usually explosive, watery stools and **fever** in a very ill-appearing infant. It is important to diagnose the condition before the intestinal obstruction causes an overgrowth of bacteria that evolves into a medical emergency. Enterocolitis can lead to severe diarrhea and massive fluid loss, which can cause death from **dehydration** unless surgery is done immediately to relieve the obstruction.

WWW.BOOKBAZ.IR

Hirschsprung's disease sometimes occurs in children with other disorders of the autonomic nervous system, such as congenital central hypoventilation syndrome, a breathing disorder. Other syndromes associated with Hirschsprung's disease include congenital deafness and Waardenburg syndrome, a genetic disorder characterized by facial abnormalities and the loss of normal pigmentation in the hair, skin, and the iris of the eye.

Diagnosis

Hirschsprung's disease in the newborn must be distinguished from other causes of intestinal obstruction. The diagnosis is suspected by the child's medical history and physical examination, especially the rectal exam. The diagnosis is confirmed by a **barium enema** x ray, which shows a picture of the bowel. The x ray will indicate if a segment of bowel is constricted, causing dilation and obstruction. A biopsy of rectal tissue will reveal the absence of the nerve fibers. Adults may also undergo manometry, a balloon study (device used to enlarge the anus for the procedure) of internal anal sphincter pressure and relaxation.

Treatment

Hirschsprung's disease is treated surgically. The goal is to remove the diseased, nonfunctioning segment of the bowel and restore bowel function. This is often done in two stages. The first stage relieves the intestinal obstruction by performing a **colostomy**. This is the creation of an opening in the abdomen (stoma) through which bowel contents can be discharged into a waste bag. When the child's weight, age, or condition is deemed appropriate, surgeons close the stoma, remove the diseased portion of bowel, and perform a "pull-through" procedure, which repairs the colon by connecting functional bowel to the anus. The pull-through operation usually establishes fairly normal bowel function.

Children with total colonic aganglionosis occasionally fail to benefit from a pull-through procedure. One option in treating these patients is the construction of an ileoanal S-pouch.

The surgeon may recommend a permanent **ostomy** if the child has Down syndrome in addition to Hirschsprung's disease, as these children usually have more difficulty with bowel control.

Prognosis

Overall, prognosis is very good. Most infants with Hirschsprung's disease achieve good bowel control after surgery, but a small percentage of children may have lingering problems with soilage or constipation. These infants are also at higher risk for an overgrowth of bacteria in the intestines, including subsequent episodes of enterocolitis, and should be closely followed by a physician. Mortality from enterocolitis or surgical complications in infancy is 25–30%.

Prevention

Hirschsprung's disease is a congenital abnormality that has no known means of prevention. It is important to diagnose the condition early in order to prevent the development of enterocolitis. **Genetic counseling** can be offered to a couple with a previous child with the disease or to an affected individual considering **pregnancy** to discuss recurrence risks and treatment options. Prenatal diagnosis is not yet available.

Hirsutism

Definition

Hirsutism is a medical condition characterized by excessive, unwanted growth of facial or body hair in women. It can result in male-pattern hair growth in

women, particularly in excessive amounts of course, heavy, pigmented hair on body areas that are typically only found on men, such as the back, chest, and face.

Description

Hirsutism is not a disease; it is a pre-determined condition caused by one's genetics. The condition usually develops during **puberty**, and it becomes more pronounced as the years go by. An inherited tendency, over-production of male hormones (androgens), medication, or disease, can cause it to appear at any age.

Women who have hirsutism usually have irregular menstrual cycles. They sometimes have small breasts and deep voices, and their muscles and genitals may become larger than women without the condition. There are two main types of hersutism: idiopathic hirsutism and secondary hirsutism.

Types of hirsutism

Idiopathic hirsutism is probably hereditary because there is usually a family history of the disorder. Women with idiopathic hirsutism have normal menstrual cycles and no evidence of conditions associated with secondary hirsutism.

Secondary hirsutism is most often associated with **polycystic ovary syndrome** (an inherited hormonal disorder characterized by menstrual irregularities, biochemical abnormalities, and **obesity**). This type of hirsutism may also be caused by the following:

- malfunctions of the pituitary or adrenal glands
- use of male hormones or minoxidil (Loniten), a drug used to widen blood vessels
- adrenal or ovarian tumors

Demographics

Women are more prone to hirsutism due to their family history (especially if such medical conditions as **congenital adrenal hyperplasia** or polycystic ovary syndrome occurs) or ethnicity (women with ancestries from the Mediterranean area, Middle East, and South Asia are more likely to have excessive hair growth). Overall, about one to three out of 20 women who have not yet started **menopause** are affected by hirsutism. Further, the University of Maryland Medical Center states that about 8% of adult women in the United States have hirsutism. In post-menopausal women, the rate of slightly excessive amounts of hair increases to about three out of four (75%) women. Excessive hair growth in post-menopausal women is called ovarian hyperthecosis.

Causes and symptoms

Hirsutism can be caused by an excess amount of male hormones (androgens), especially testosterone. High androgen levels can be caused by polycystic ovary syndrome, Cushing's syndrome, congenital adrenal hyperplasia, tumors, and medication. Hirsutism can also be caused by a family trait or an ethnic predisposition. Obesity in women increases their risk to excessive hair growth, primarily because of higher levels of insulin in overweight and obese people (which causes ovarian theca cells to produce male hormones). Hirsutism is rarely caused by a serious underlying disorder. **Pregnancy** occasionally stimulates its development. Further, hirsutism is almost never triggered by tumors. Sometimes no cause can be pinpointed for excessive hair growth in women. When an identifiable cause cannot be determined then excessive hair growth is called idiopathic hirsutism. This type of hirsutism is associated with certain ethnic backgrounds, such as women of Mediterranean, Middle Eastern, and South Asian descent.

When hirsutism occurs hair follicles usually become enlarged, and the hairs themselves become larger and darker. Significant hair growth may initially appear on any of the following: chin, sideburn area on face, around the nipples on the breast, lower abdomen, and upper lip. Later, hair growth may be seen on the following: upper back, sternum, shoulders, and upper abdomen. A woman whose hirsutism is caused by an increase in male hormones has a pattern of hair growth similar to that of a man. When male hormones are the cause, other symptoms appear over time in a process called virilization. These symptoms include:

- developing acne
- balding (alopecia) or receding hairline
- decreasing breast size
- decreasing feminine body shape
- deepening voice
- enlarging of the clitoris
- increasing irregular menstrual periods
- increasing mass of the muscles, especially enlarged shoulder muscles
- developing oily skin

By contrast, a woman whose hirsutism is not hormone-related has long, fine hairs on her face, arms, chest, and back.

Diagnosis

According to the Mayo Clinic, a medical professional should be consulted when any of the following has developed:

WWW.BOOKBAZ.IR

- Rapidly growing, unwanted hair on places such as the upper lip, cheeks, chin, neck, midchest, inner thighs or low back
- Unwanted hair growth associated with irregular menstrual periods
- Male features, such as a deepening voice, balding, increased muscle mass and decreased breast size
- Unwanted hair growth that appears to be worsened by a medication

Diagnosis is based on a family history of hirsutism, a personal history of menstrual irregularities, and masculine traits. Laboratory tests are not needed to assess the status of patients whose menstrual cycles are normal and who have mild, gradually progressing hirsutism.

A family physician or endocrinologist may order blood tests to measure hormone levels in women with long-standing menstrual problems or more severe hirsutism. The hormones dehydroepiandrosterone and testosterone can be tested to check for adrenal gland tumors, adrenal gland hormone deficiencies, polycystic ovary syndrome, and ovary tumors. The hormone prolactin is often checked to determine if a tumor is present in the pituitary gland. **Cholesterol** and sugar levels are frequently tested to determine if high levels of cholesterol and diabetes, respectively, are present, because both are associated with higher risk for hirsutism.

If further testing is needed, **ultrasound** may be used to produce images of the ovaries or adrenal glands to check for tumors or cysts. Computed tomography (CT) scans are sometimes performed to evaluate diseases of the adrenal glands. Additional diagnostic procedures, such as **magnetic resonance imaging** (MRI) of the brain, may be used to confirm or rule out underlying diseases or disorders.

Women who are approaching menopause or in the early years of menopause may develop coarse chin or other unwanted facial hair, but this change is the result of their normal hormonal changes caused by menopause.

Treatment

Treatment for hirsutism is effective when a combination of self-care and medical therapies are used. Primary hirsutism can be treated mechanically. Mechanical treatment involves bleaching or physically removing unwanted hair by any of the following methods:

- cutting
- electrolysis
- shaving
- tweezing
- waxing
- using hair-removing creams (depilatories)

Electrolysis is used by inserting a tiny needle into hair follicles in order to eventually destroy them with pulses of electric current. The process can be painful and results in permanent hair removal. Waxing should be performed every four to six weeks to be effective. Most of these treatment options, which must be repeated periodically, cause skin irritation.

Laser therapy may be used by directing a beam of concentrated light over the skin in order to damage hair follicles. Some skin discomfort may be felt during the process. The affected area may become red and swollen afterwards. Some hair regrowth may occur, which can be eliminated with follow-up laser treatments.

Low-dose dexamethasone (a synthetic adrenocortical steroid), birth-control pills, or medications that suppress male hormones (for example, spironolactone) may be prescribed for patients whose condition stems from high androgen levels. Topical creams such as eflornithine (Vaniqa) can be prescribed to treat excessive facial hair in women. The creams do not eliminate existing hair, only slows the growth of new hairs. Tingling or stinging of the skin may occur, along with a skin rash.

Treatment of secondary hirsutism is determined by the underlying cause of the condition.

Prescription medications to treat hirsutism have not yet been approved for use in the United States by the Food and Drug Administration (FDA).

Alternatives

Plucking hairs with tweezers, shaving, waxing, and using chemical depilatories are all alternative ways to remove unwanted hair. Bleaching removes the color of the hair but does not remove the hair itself.

In addition, altering one's lifestyle and diet can reduce the amount of male hormones produced by the body. Such lifestyle and diet changes include:

- drinking plenty of filtered water daily
- eating fruits and vegetables high in antioxidants such as blueberries, cherries, tomatoes, squash, and bell peppers
- eating less or eliminating red meets from the diet; substituting leaner meats, fish, and beans
- eating less refined foods such as pastas and white bread and others high in sugar

KEY TERMS

Androgens—Another name for male hormones.

Congenital adrenal hyperplasia—A hormonal disorder among women of reproductive age in which the ovaries tend to be enlarged and contain numerous small cysts along the outer edge of each ovary.

Computed tomography (CT)—Also called computerized tomography, a series of x-ray scans taken from many different angles and processed to make cross-sectional images of soft tissues and bones inside the body.

Congenital adrenal hyperplasia—A hormonal disorder among women of reproductive age in which the ovaries in most cases are enlarged and contain numerous small cysts along the outer edge of each ovary.

Magnetic resonance imaging (MRI)—A medical test that uses a magnetic field and pulses of radiowave energy to produce images of organs and structures located in the interior of the human body.

Polycystic ovary syndrome (PCOS)—A common endocrine disorder among females, which is likely to be genetically determined.

Ultrasound—A diagnostic imaging technique used for visualizing subcutaneous body structures, including internal organs, joints, muscles, and tendons, for possible pathology or lesions.

- eliminating trans fat from the diet, such as from commercially produced bakery goods, French fries, donuts, processed foods, and some margarines
- exercising at least 30 minutes daily for at least five days a week
- reducing or eliminating alcohol and tobacco
- using healthy oils when cooking and eating such as olive oil

Prognosis

Birth-control pills alone cause this condition to stabilize in one of every two patients and to improve in one of every ten.

When spironolactone (Aldactone) is prescribed to suppress hair growth, 70% of patients experience improvement within six months. When women also take birth-control pills, menstrual cycles become regular, and hair growth is suppressed even more.

Before taking medicines for hirsutism women should consult with a medical professional if they are within childbearing years. Women are advised not to become pregnant while taking such medications.

Prevention

Hirsutism is generally not preventable. However, if women have certain medical conditions, such as polycystic ovary syndrome, then hirsutism can be controlled.

Histiocytosis X

Definition

Histiocytosis X is a generic term that refers to an increase in the number of histiocytes, a type of white

WWW.BOOKBAZ.IR

blood cell, that act as scavengers to remove foreign material from the blood and tissues. Since recent research demonstrated Langerhan cell involvement as well as histiocytes, this led to a proposal that the term Langerhans Cell Histiocytosis (LCH) be used in place of histiocytosis X. Either term refers to three separate illnesses (listed in order of increasing severity): eosinophilic granuloma, Hand-Schuller-Christian disease, and Letterer-Siwe disease.

Description

Epidermal (skin) Langerhans cells (a form of dendritic cell) accumulate with other immune cells in various parts of the body and cause damage by the release of chemicals. Normally, Langerhans cells recognize foreign material, including bacteria, and stimulate the immune system to react to them. Langerhans cells are usually found in skin, lymph nodes, lungs, and the gastrointestinal tract. Under abnormal conditions these cells affect skin, bone, and the pituitary gland as well as the lungs, intestines, liver, spleen, bone marrow, and brain. Therefore, the disease is not confined to areas where Langerhans cells are normally found. The disease is more common in children than adults and tends to be most severe in very young children.

Histiocytosis X or LCH is a family of related conditions characterized by a distinct inflammatory and proliferative process but differs from each other in which parts of the body are involved. The least severe of the histiocytosis X/LCH family is eosinophilic granuloma. Approximately 60–80% of all diagnosed cases are in this classification, which usually occurs in children aged 5–10 years. The bones are involved 50–75% of the time, which includes the skull or mandible, and the long bones. If the bone marrow is involved, anemia can result. With skull involvement, growths can occur behind the eyes, bulging them forward. One case study involved swelling of the eyes caused by histiocytosis in a three-year-old girl. The lungs are involved less than 10% of the time, and this involvement signals the worst prognosis.

Next in severity is Hand-Schuller-Christian disease, a chronic, scattered form of histiocytosis. It occurs most commonly from age 1–3 years and is a slowly progressive disease that affects the softened areas of the skull, other flat bones, the eyes, and skin. Letterer-Siwe disease is the acute form of this series of diseases. It is generally found from the time of birth to one year of age. It causes an enlarged liver, bruising and **skin lesions**, anemia, enlarged lymph glands, other organ involvement, and extensive skull lesions.

Causes and symptoms

This is a rare disorder affecting approximately 1 in 200,000 children or adults each year. The International Histiocyte Society formed a registry in 2000 that has registered a total of about 300 adults from 13 countries. Because histiocytic disorders are so rare, little research has been done to determine their cause. Over time, histiocytosis may lessen in its assault on the body but there are still problems from damage to the tissues. There are no apparent inheritance patterns in these diseases with the exception of a form involving the lymphatic system; of the 274 adults in the international registry, only one came from a family with a history of the disease.

The symptoms of histiocytosis are caused by substances called cytokines and prostaglandins, which are normally produced by histiocytes and act as messengers between cells. When these chemicals are produced in excess amounts and in the wrong places, they cause tissue swelling and abnormal growth. Thus, symptoms may include painful lumps in the skull and limbs as well as **rashes** on the skin. General symptoms may include: poor appetite, failure to gain weight, recurrent **fever**, and irritability. Symptoms from other possible sites of involvement include:

- gums: swelling, often without significant discomfort
- ear: chronic discharge
- liver or spleen: abdominal discomfort or swelling
- pituitary: This gland at the base of the brain is affected at some stage in approximately 20–30% of children causing a disturbance in water balance to produce thirst and frequent urination.
- eyes: Due to the bony disease, behind-the-eye bulging may occur (exophthalmos).
- lungs: breathing problems

Diagnosis

The diagnosis can be made only by performing a biopsy, that is, taking a tissue sample under **anesthesia** from a site in the patient thought to be involved. Blood and urine tests, chest and other x rays, **magnetic resonance imaging** (MRI) and **computed tomography scans** (CT scans) (to check the extent of involvement), and possibly bone marrow or breathing tests may be required to confirm the diagnosis.

Treatment

Although this disease is not cancer, most patients diagnosed with it are treated in cancer clinics. There are two reasons for this:

- Historically, cancer specialists treated it before the cause was known.
- The treatment requires the use of drugs typically required to treat cancer.

Cancer drugs utilized are usually given in smaller doses, which diminishes the severity of their side effects. **Radiation therapy** is rarely used, and special drugs may be prescribed for skin symptoms. If only one organ is affected, **steroids** may be injected locally, or a drug called indomethacin may be used. Indomethacin is an anti-inflammatory medication that may achieve a similar response with less severe side effects.

Prognosis

The disease fluctuates markedly. If only one system is involved, the disease often resolves by itself. Multisystem disease usually needs treatment, although it may disappear spontaneously. The disease is not normally fatal unless organs vital to life are damaged. In general, the younger the child at diagnosis and the more organs involved, the poorer the outlook. If the condition resolves, there could still be long-term complications because of damage done while the disease was active.

Histoplasmosis

Definition

Histoplasmosis is an **infectious disease** caused by inhaling the microscopic spores of the fungus *Histoplasma capsulatum*. The disease exists in three forms. Acute or primary histoplasmosis causes flu-like symptoms. Most people who are infected recover without medical intervention. Chronic histoplasmosis affects the lungs and can be fatal. Disseminated histoplasmosis affects many organ systems in the body and is often fatal, especially to people with acquired **immunodeficiency** syndrome (**AIDS**).

Description

Histoplasmosis is an airborne infection. The spores that cause this disease are found in soil that has been contaminated with bird or bat droppings. In the United States, the disease is most common in eastern and midwestern states and is widespread in the upper Mississippi, Ohio, Missouri, and St. Lawrence river valleys. Sometimes histoplasmosis is called Ohio Valley disease, Central Mississippi River Valley disease, Appalachian Mountain disease, Darling's disease, or *Histoplasma capsulatum* infection.

Anyone can get histoplasmosis, but people who come in contact with bird and bat excrement are more likely to be infected. This includes farmers, gardeners, bridge inspectors and painters, roofers, chimney cleaners, demolition and construction workers, people installing or servicing heating and air conditioning units, people restoring old or abandoned buildings, and people who explore caves.

The very young and the elderly, especially if they have a pre-existing lung disease or are heavy smokers, are more likely to develop symptoms that are more severe. People who have a weakened immune system, either from diseases, such as AIDS or leukemia, or as the result of medications they take (**corticosteroids**, **chemotherapy** drugs), are more likely to develop chronic or disseminated histoplasmosis.

Causes and symptoms

When the spores of *H. capsulatum* are inhaled, they lodge in the lungs where they divide and cause lesions. This is known as acute or primary histoplasmosis. It is not contagious.

Many otherwise healthy people show no symptoms of infection at all. When symptoms do occur, they appear 3–17 days after exposure (average time is 10 days). The symptoms are usually mild and resemble

WWW.BOOKBAZ.IR

those of a cold or flu: **fever**, dry **cough**, enlarged lymph glands, tiredness, and a general feeling of ill health. A small number of people develop bronchopneumonia. About 95% of people who are infected either experience no symptoms or have symptoms that clear up spontaneously. These people then have partial immunity to re-infection.

In some people, the spores that cause the disease continue to live in the lungs. In about 5% of people who are infected, usually those with chronic lung disease, diabetes mellitis, or weakened immune systems, the disease progresses to chronic histoplasmosis. This can take months or years. Symptoms of chronic histoplasmosis resemble those of **tuberculosis**. Cavities form in the lung tissue, parts of the lung may collapse, and the lungs fill with fluid. Chronic histoplasmosis is a serious disease that can result in death.

The most rare form of histoplasmosis is disseminated histoplasmosis. Disseminated histoplasmosis is seen almost exclusively in patients with AIDS or other immune defects. In disseminated histoplasmosis the infection may move to the spleen, liver, bone marrow, or adrenal glands. Symptoms include a worsening of those found in chronic histoplasmosis, as well as weight loss, **diarrhea**, the development of open sores in the mouth and nose, and enlargement of the spleen, liver, and adrenal gland.

Diagnosis

A simple skin test similar to that given for tuberculosis will tell if a person has previously been infected by the fungus *H. capsulatum*. Chest x rays often show lung damage caused by the fungus, but do not lead to a definitive diagnosis because the damage caused by other diseases has a similar appearance on the x ray. Diagnosis of chronic or disseminated histoplasmosis can be made by culturing a sample of sputum or other body fluids in the laboratory to isolate the fungus. The urine, blood serum, washings from the lungs, or cerebrospinal fluid can all be tested for the presence of an antigen produced in response to the infection. Most cases of primary histoplasmosis go undiagnosed.

Treatment

Acute primary histoplasmosis generally requires no treatment other than rest. Non-prescription drugs such as **acetaminophen** (Tylenol) may be used to treat **pain** and relieve fever. Avoiding smoke and using a cool air humidifier may ease chest pain.

Patients with an intact immune system who develop chronic histoplasmosis are treated with the drug ketoconazole (Nizoral) or amphotericin B (Fungizone). Patients with suppressed immune systems are treated with amphotericin B, which is given intravenously. Because of its potentially toxic side effects, hospitalization is often required. The patient may also receive other drugs to minimize the side effects of the amphotericin B.

Patients with AIDS must continue to take the drug itraconazole (Sporonox) orally for the rest of their lives in order to prevent a relapse. If the patient can not tolerate itraconazole, the drug fluconazole (Diflucan) can be substituted.

Alternatives

In non-immunocompromised patients, alternative therapies can be very successful. Alternative treatment for **fungal infections** focuses on creating an environment where the fungus cannot survive. This is accomplished by maintaining good health and eating a diet low in dairy products; sugars, including honey and fruit juice; and foods like beer that contain yeast. This is complemented by a diet high in raw food. Supplements of antioxidant **vitamins** C, E, and A, along with B complex, may also be added to the diet. *Lactobacillus acidophilus* and *Bifodobacteria* will replenish the good bacteria in the intestines. Antifungal herbs, like garlic, can be consumed in relatively large doses and for an extended period of time in order to be most effective.

Prognosis

Most people recover from primary histoplasmosis in a few weeks without medical intervention. Patients with chronic histoplasmosis who are treated with antifungal drugs generally recover rapidly if they do not have an underlying serious disease. When left untreated, or if serious disease is present, histoplasmosis can be fatal.

AIDS patients with disseminated histoplasmosis vary in their response to amphotericin B, depending on their general health and how well they tolerate the side effects of the drug. Treatment often suppresses the infection temporarily, but patients with AIDS are always in danger of a relapse and must continue to take medication for the rest of their lives to keep the infection at bay. New combinations of therapies and new drugs are constantly being evaluated, making hard statistics on prognosis difficult to ascertain. AIDS patients have problems with multiple opportunistic infections, making it difficult to isolate death rates due to any one particular fungal infection.

Prevention

Since the spores of *H. capsulatum* are so widespread, it is almost impossible to prevent exposure in endemic areas. Dust suppression measures when

working with contaminated soil may help limit exposure. Individuals who are at risk of developing the more severe forms of the disease should avoid situations where they will be exposed to bat and bird droppings.

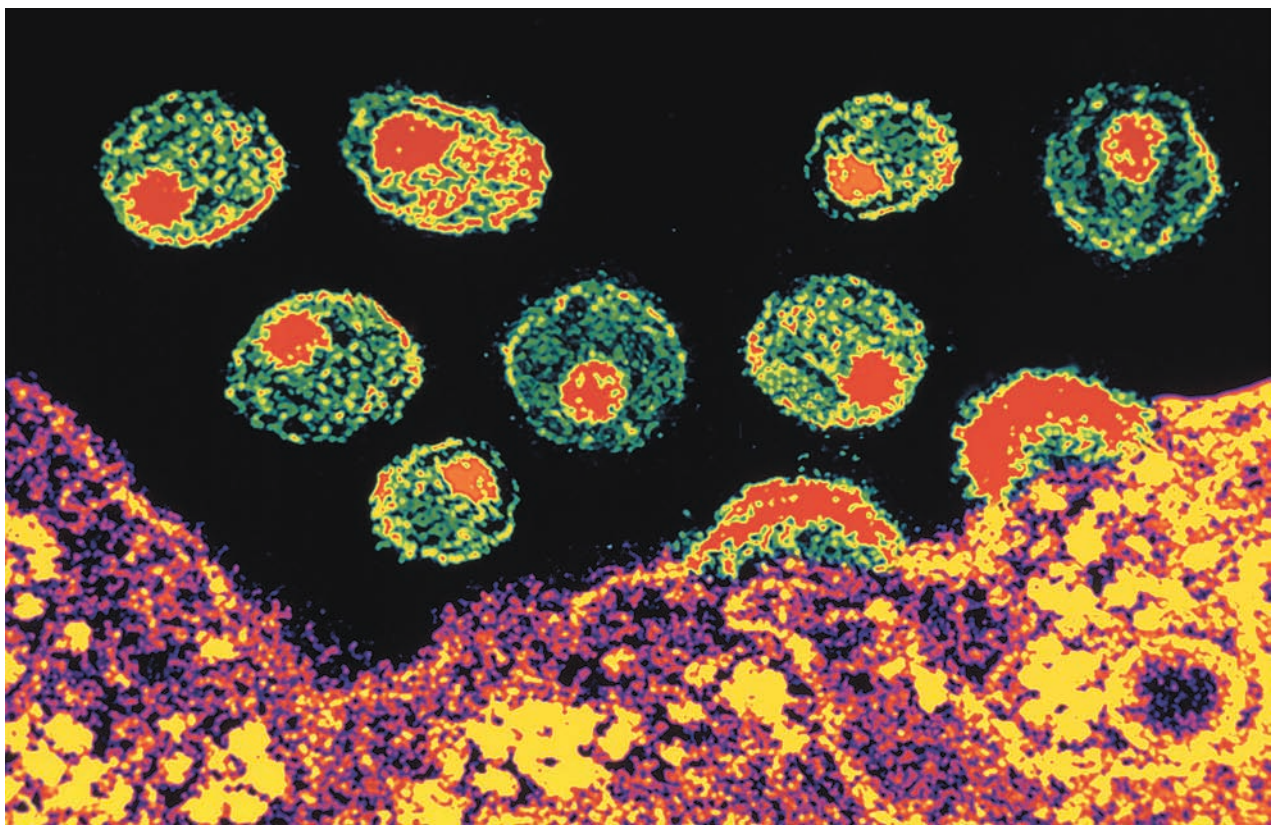
HIV and AIDS tests

Definition

AIDS tests, short for acquired **immunodeficiency** syndrome tests, cover a number of different procedures used in the diagnosis and treatment of HIV patients. These tests sometimes are called AIDS serology tests. Serology is the branch of immunology that deals with the contents and characteristics of blood serum. Serum is the clear light yellow part of blood that remains liquid when blood cells form a clot. AIDS serology evaluates the presence of human immunodeficiency virus (HIV) infection in blood serum and its effects on each patient's immune system.

Purpose

AIDS serology serves several different purposes. Some AIDS tests are used to diagnose patients or confirm a diagnosis; other tests are used to measure the progression of the disease or the effectiveness of specific treatment regimens. Some AIDS tests also can be used to screen blood donations for safe use in transfusions.



Mature HIV-1 viruses (above) and the lymphocyte from which they emerged (below). Two immature viruses can be seen budding on the surface of the lymphocyte (right of center). *(Scott Camazir/Photo Researchers, Inc.)*

WWW.BOOKBAZ.IR

In order to understand the different purposes of the blood tests used with AIDS patients, it is helpful to understand how HIV infection affects human blood and the immune system. HIV is a retrovirus that enters the bloodstream of a new host in the following ways:

- by sexual contact
- by contact with infected body fluids (such as blood and urine)
- by transmission during pregnancy
- through transfusion of infected blood products

A retrovirus is a virus that contains a unique enzyme called reverse transcriptase that allows it to replicate within new host cells. The virus binds to a protein called CD4, which is found on the surface of certain subtypes of white blood cells, including helper T cells, macrophages, and monocytes. Once HIV enters the cell, it can replicate and kill the cell in ways that are still not completely understood. In addition to killing some lymphocytes directly, the AIDS virus disrupts the functioning of the remaining CD4 cells. CD4 cells ordinarily produce a substance called interleukin-2 (IL-2), which stimulates other cells (T cells and B cells) in the human immune system to respond to infections. Without the IL-2, T cells do not reproduce as they normally would in response to the HIV virus, and B cells are not stimulated to respond to the infection.

Precautions

In some states, such as New York, a signed consent form is needed in order to administer an AIDS test. As with all blood tests, healthcare professionals should always wear gloves and avoid being pricked by the needle used in drawing blood for the tests. It may be difficult to get blood from a habitual intravenous drug user due to collapsed veins.

Description

Diagnostic tests

Diagnostic blood tests for AIDS usually are given to persons in high-risk populations who may have been exposed to HIV or who have the early symptoms of AIDS. Most persons infected with HIV will develop a detectable level of antibody within three months of infection. The condition of testing positive for HIV antibody in the blood is called seroconversion, and persons who have become HIV-positive are called seroconverters.

It is possible to diagnose HIV infection by isolating the virus itself from a blood sample or by demonstrating the presence of HIV antigen in the blood. Viral culture, however, is expensive, not widely available, and slow—it takes 28 days to complete the viral culture test. More common are blood tests that work by detecting the presence of antibodies to the HIV virus. These tests are inexpensive, widely available, and accurate in detecting 99.9% of AIDS infections when used in combination to screen patients and confirm diagnoses.

Diagnosis of HIV infection can be determined by detecting antibodies to the virus (the most widely used method), detecting the viral p24 antigen, detecting viral nucleic acid (NAT), or culturing HIV. The accuracy of HIV serologic testing is extremely high. Fourth-generation diagnostic assays have increased sensitivity so the "window period" during which the virus cannot be detected after infection with the virus has shortened.

An at-home oral HIV test is available for detecting HIV antibodies to HIV-1 and HIV-2, but not the virus itself. This test, called OraQuick, was approved by the FDA in 2012, for use by adults 17 years of age or older. The test uses oral fluid obtained from around the gums to check for HIV. It is considered a screening test only, so individuals should also seek testing and advice from a trusted health professional for further advice and care.

ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA). This type of blood test is used to screen blood for transfusions as well as diagnose patients. An ELISA test for HIV works by attaching HIV antigens to a plastic well or beads. A sample of the patient's blood serum is added, and excess proteins are removed. A second antibody coupled to an enzyme is added, followed by addition of a substance that will cause the enzyme to react by forming a color. An instrument called a spectrophotometer can measure the color. The name of the test is derived from the use of the enzyme that is coupled or linked to the second antibody.

The latest generation of ELISA tests are 99.5% sensitive to HIV. Occasionally, the ELISA test will be positive for a patient without symptoms of AIDS from a low-risk group. Because this result is likely to be a false-positive, the ELISA must be repeated *on the same sample of the patient's blood*. If the second ELISA is positive, the result should be confirmed by the Western blot test.

The standard test for antibodies to HIV is an enzyme immunoassay (EIA) screening assay with a confirmatory Western blot performed on EIA-positive specimens to exclude a false positive test.

WESTERN BLOT (IMMUNOBLOT). The Western blot or immunoblot test is used as a reference procedure to

confirm the diagnosis of AIDS. In Western blot testing, HIV antigen is purified by electrophoresis (in which large protein molecules are suspended in a gel and separated from one another by running an electric current through the gel). The HIV antigens are attached by blotting to a nylon or nitrocellulose filter. The patient's serum is reacted against the filter, followed by treatment with developing chemicals that allow HIV antibody to show up as a colored patch or blot. A commercially produced Western blot test for HIV-1 is available. It consists of a prefabricated strip that is incubated with a sample of the patient's blood serum and the developing chemicals. About nine different HIV-1 proteins can be detected in the blots.

When used in combination with ELISA testing, Western blot testing is 99.9% specific. It can yield false negatives in patients with very early HIV infection and in those infected by HIV-2. In some patients the Western blot yields indeterminate results.

IMMUNOFLUORESCENCE ASSAY (IFA). This method is sometimes used to confirm ELISA results instead of Western blotting. An IFA test detects the presence of HIV antibody in a sample of the patient's serum by mixing HIV antigen with a fluorescent chemical, adding the blood sample, and observing the reaction under a microscope with ultraviolet light.

POLYMERASE CHAIN REACTION (PCR). This test is used to evaluate the very small number of AIDS patients with false-negative ELISA and Western blot tests. These patients are sometimes called antibody-negative asymptomatic (without symptoms) carriers, because they do not have any symptoms of AIDS and there is no detectable quantity of antibody in the blood serum. Antibody-negative asymptomatic carriers may be responsible for the very low ongoing risk of HIV infection transmitted by blood transfusions. It is estimated that the risk is between one in 10,000 and one in 100,000 units of transfused blood.

The polymerase chain reaction (PCR) test can measure the presence of viral nucleic acids in the patient's blood even when there is no detectable antibody to HIV. This test works by amplifying the presence of HIV nucleic acids in a blood sample. Numerous copies of a gene are made by separating the two strands of DNA containing the gene segment, marking its location, using DNA polymerase to make a copy, and then continuously replicating the copies. It is questionable whether PCR will replace Western blotting as the method of confirming AIDS diagnoses. Although PCR can detect the low number of persons (1%) with HIV infections that have not yet generated an antibody response to the virus, the overwhelming majority of infected persons will be detected by ELISA screening within one to three months of infection. In addition, PCR testing is based on present knowledge of the genetic sequences in HIV. Since the virus is continually generating new variants, PCR testing could yield a false negative in patients with these new variants. In 2004, researchers reported on a new test that was more sensitive to HIV, detecting the infection in as little as 12 days after infection. The manufacturer was still seeking FDA approval for the test, which would cost about the same as PCR testing.

Consumer testing

In 1999, the U.S. Food and Drug Administration (FDA) approved an HIV home testing kit. The kit containes multiple components, including material for specimen collection, a mailing envelope to send the specimen to a laboratory for analysis, and provides pre- and post-test counseling. It uses a finger prick process for blood collection. More recently, tests have been developed that allow patients to monitor their own therapy in the home without sending out for results.

Consumers now have the ability to perform private in-home testing for HIV using the OraQuick test. In 2012, the FDA approved this first self-administered HIV test kit. Results are available in 20–40 minutes. Findings from the test need to be confirmed with a standard HIV antibody test.

Prognostic tests

Blood tests to evaluate patients already diagnosed with HIV infection are as important as the diagnostic tests. Because AIDS has a long latency period, some persons may be infected with the virus for 10 years or longer before they develop symptoms of AIDS. These patients are sometimes called antibody-positive asymptomatic carriers. Prognostic tests also help drug researchers evaluate the usefulness of new medications in treating AIDS.

BLOOD CELL COUNTS. Doctors can measure the number or proportion of certain types of cells in an AIDS patient's blood to see whether and how rapidly the disease is progressing, or whether certain treatments are helping the patient. These cell count tests include:

- Complete blood count (CBC). A CBC is a routine analysis performed on a sample of blood taken from the patient's vein with a needle and vacuum tube. The measurements taken in a CBC include a white blood cell count (WBC), a red blood cell count (RBC), the red cell distribution width, the hematocrit

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A protein in the blood that identifies and helps remove disease organisms or their toxins. Antibodies are secreted by B cells. AIDS diagnostic tests work by demonstrating the presence of HIV antibody in the patient's blood.

Antigen—Any substance that stimulates the body to produce antibodies.

B cell—A type of white blood cell derived from bone marrow. B cells are sometimes called B lymphocytes. They secrete antibody and have a number of other complex functions within the human immune system.

CD4—A type of protein molecule in human blood that is present on the surface of 65% of human T cells. CD4 is a receptor for the HIV virus. When the HIV virus infects cells with CD4 surface proteins, it depletes the number of T cells, B cells, natural killer cells, and monocytes in the patient's blood. Most of the damage to an AIDS patient's immune system is done by the virus' destruction of CD4+ lymphocytes. CD4 is sometimes called the T4 antigen.

Complete blood count (CBC)—A routine analysis performed on a sample of blood taken from the patient's vein with a needle and vacuum tube. The measurements taken in a CBC include a white blood cell count, a red blood cell count, the red cell distribution width, the hematocrit (ratio of the volume of the red blood cells to the blood volume), and the amount of hemoglobin (the blood protein that carries oxygen). CBCs are a routine blood test used for many medical reasons, not only for AIDS patients. They can help the doctor determine whether a patient is in advanced stages of the disease.

Electrophoresis—A method of separating complex protein molecules suspended in a gel by running an electric current through the gel.

Enzyme-linked immunosorbent assay (ELISA)—A diagnostic blood test used to screen patients for AIDS or other viruses. The patient's blood is mixed with antigen attached to a plastic tube or bead surface. A sample of the patient's blood serum is added, and excess proteins are removed. A second antibody coupled to an enzyme is added, followed by a chemical that will cause a color reaction that can be measured by a special instrument.

Human immunodeficiency virus (HIV)—A transmissible retrovirus that causes AIDS in humans. Two forms of HIV are now recognized: HIV-1, which causes most cases of AIDS in Europe, North and South America, and most parts of Africa; and HIV-2, which is chiefly found in West African patients. HIV-2, discovered in 1986, appears to be less virulent than HIV-1, but may have a longer latency period.

Human immunodeficiency virus groups—HIV classification has evolved into several groups, allowing for further distinction; specific lineages are now termed as groups M, N, O, and P. M is considered the pandemic strain and comprises the vast majority of strains of HIV. Viruses from the M group are then divided into subtypes, of which there are 10 identified currently (A–J). Subtypes are also known as clades. The most common clade in the United States and Europe is HIV clade B; HIV testing was originally developed to identify HIV clade B.

(ratio of the volume of the red blood cells to the blood volume), and the amount of hemoglobin (the blood protein that carries oxygen). Although CBCs are used on more than just AIDS patients, they can help the doctor determine whether an AIDS patient has an advanced form of the disease. Specific AIDS-related signs in a CBC include a low hematocrit, a sharp decrease in the number of blood platelets, and a low level of a certain type of white blood cell called neutrophils.

- Absolute CD4+ lymphocytes. A lymphocyte is a type of white blood cell that is important in the formation of an immune response. Because HIV targets CD4+ lymphocytes, their number in the patient's blood can be used to track the course of the infection. This blood cell count is considered the most accurate indicator of the presence of an opportunistic infection in an AIDS patient. The absolute CD4+ lymphocyte count is obtained by multiplying the patient's white blood cell count (WBC) by the percentage of lymphocytes among the white blood cells, and multiplying the result by the percentage of lymphocytes bearing the CD4+ marker. An absolute count below 200–300 CD4+ lymphocytes in 1 cubic millimeter (mm^3) of blood indicates that the patient is vulnerable to some opportunistic infections.
- CD4+ lymphocyte percentage. Some doctors think this is a more accurate test than the absolute count

Immunofluorescence assay (IFA)—A blood test sometimes used to confirm ELISA results instead of using the Western blotting. In an IFA test, HIV antigen is mixed with a fluorescent compound and then with a sample of the patient's blood. If HIV antibody is present, the mixture will fluoresce when examined under ultraviolet light.

Lymphocyte—A type of white blood cell that is important in the formation of antibodies. Doctors can monitor the health of AIDS patients by measuring the number or proportion of certain types of lymphocytes in the patient's blood.

Macrophage—A large white blood cell, found primarily in the bloodstream and connective tissue, that helps the body fight off infections by ingesting the disease organism. HIV can infect and kill macrophages.

Monocyte—A large white blood cell that is formed in the bone marrow and spleen. About 4% of the white blood cells in normal adults are monocytes.

Opportunistic infection—An infection that develops only when a person's immune system is weakened, as happens to AIDS patients.

Polymerase chain reaction (PCR)—A test performed to evaluate false-negative results to the ELISA and Western blot tests. In PCR testing, numerous copies of a gene are made by separating the two strands of DNA containing the gene segment, marking its location, using DNA polymerase to make a copy, and then continuously replicating the copies. The amplification of gene sequences that are associated with HIV allows for detection of the virus by this method.

Retrovirus—A virus that contains a unique enzyme called reverse transcriptase that allows it to replicate within new host cells.

Seroconversion—The change from HIV-negative to HIV-positive status during blood testing.

Serology—The analysis of the contents and properties of blood serum.

Serum—The part of human blood that remains liquid when blood cells form a clot. Human blood serum is clear light yellow in color.

T cells—Lymphocytes that originate in the thymus gland. T cells regulate the immune system's response to infections, including HIV. CD4 lymphocytes are a subset of T lymphocytes.

Viral load test—A new blood test for monitoring the speed of HIV replication in AIDS patients. The viral load test is based on PCR techniques and supplements the CD4+ cell count tests.

WBC differential—A white blood cell count in which the technician classifies the different white blood cells by type as well as calculating the number of each type. A WBC differential is necessary to calculate the absolute CD4+ lymphocyte count.

Western blot—A technique developed in 1979 that is used to confirm ELISA results. HIV antigen is purified by electrophoresis and attached by blotting to a nylon or nitrocellulose filter. The patient's serum is reacted against the filter, followed by treatment with developing chemicals that allow HIV antibody to show up as a colored patch or blot. If the patient is HIV-positive, there will be stripes at specific locations for two or more viral proteins. A negative result is blank.

because the percentage does not depend on a manual calculation of the number of types of different white blood cells. A white blood cell count that is broken down into categories in this way is called a WBC differential.

It is important for doctors treating AIDS patients to measure the lymphocyte count on a regular basis. Experts consulted by the U.S. **Public Health** Service recommend the following frequency of serum testing based on the patient's CD4+ level:

- CD4+ count more than 600 cells/mm^3: Every six months
- CD4+ count between 200 and 600 cells/mm^3: Every three months
- CD4+ count less than 200 cells/mm^3: Every three months

When the CD4+ count falls below 200 cells/mm^3, the doctor will put the patient on a medication regimen to protect him or her against opportunistic infections.

HIV VIRAL LOAD TESTS. Another type of blood test for monitoring AIDS patients is the viral load test. It supplements the CD4+ count, which can tell the doctor the extent of the patient's loss of immune function, but not the speed of HIV replication in the body. HIV viral load reflects a patient's response to antiviral therapy and indicates the course of the disease more

WWW.BOOKBAZ.IR

accurately than any other test, including CD4 T cell counts.

The viral load test is based on PCR techniques and can measure the number of copies of HIV nucleic acids. Successive test results for a given patient's viral load are calculated on a base 10 logarithmic scale.

ORAL HIV TESTS. Scientists have developed oral HIV tests that can be conducted with saliva samples. One of the unintended effects of these tests is the misperception that HIV can be transmitted through saliva. Still, they present an excellent alternative to blood sample testing.

RAPID HIV TESTS. Researchers constantly work on more rapid tests for HIV that can be done in physician offices and in more convenient locations in developing countries. A finger-stick test that can be read quickly from a whole blood sample had shown promising results in the fall of 2003. Another test, called the VScan test kit, requires no refrigeration or electricity and can safely be stored at room temperature. Even if the positive results must be confirmed by ELISA or Western blotting, an accurate initial rapid test can help screen populations for HIV antibodies.

In 2004, a new three-minute test for HIV was launched in the United States under FDA approval. This test allows health care providers such as family practice physician offices to quickly test a patient in the office and provide results while the patient waits, rather than sending results to a lab.

In 2013, the FDA approved the first rapid HIV test designed to detect HIV-1 antigen, and HIV-1 and HIV-2 antibodies in human serum, plasma, and blood specimens (blood may be obtained via a finger stick). The test, performed by trained professionals, can help identify HIV-infected individuals who may visit clinics and other outpatient settings outside of a hospital environment. This test can reach individuals living in outlying or remote areas easier, allowing for faster diagnosis and medical treatment. The test, called the Alere Determine HIV-1/2 Ag/Ab Combo test, is manufactured by a company in Yavne, Israel.

BETA$_2$-MICROGLOBULIN (BETA$_{2M}$). Beta$_2$-microglobulin is a protein found on the surface of all human cells with a nucleus. It is released into the blood when a cell dies. Although rising blood levels of Beta$_{2M}$ are found in patients with cancer and other serious diseases, a rising Beta$_{2M}$ blood level can be used to measure the progression of AIDS.

P24 ANTIGEN CAPTURE ASSAY. Found in the viral core of HIV, p24 is a protein that can be measured by the ELISA technique. Doctors can use p24 assays to measure the antiviral activity of the patient's medications. In addition, the p24 assay is sometimes useful in detecting HIV infection before seroconversion. However, p24 is consistently present in only 25% of persons infected with HIV.

GENOTYPIC DRUG RESISTANCE TEST. Genotypic testing can help determine whether specific gene mutations, common in people with HIV, are causing drug resistance and drug failure. The test looks for specific genetic mutations within the virus that are known to cause resistance to certain drugs used in HIV treatment. For example the drug 3TC, also known as lamivudine (Epivir), is not effective against strains of HIV that have a mutation at a particular position on the reverse transcriptase protein—amino acid 184, known as M184V (M→V, methionine to valine). If the genotypic resistance test shows a mutation at position M184V, it is likely the person is resistant to 3TC and not likely to respond to 3TC treatment. Genotypic tests are only effective if the person is already taking antiviral medication and if the viral load is greater than 1,000 copies per milliliter (mL) of blood. The cost of the test, usually between $300 and $500, is now covered by many insurance plans.

PHENOTYPIC DRUG RESISTANCE TESTING. Phenotypic testing directly measures the sensitivity of a patient's HIV to particular drugs and drug combinations. To do this, it measures the concentration of a drug required to inhibit viral replication in the test tube. This is the same method used by researchers to determine whether a drug might be effective against HIV before using it in human clinical trials. Phenotypic testing is a more direct measurement of resistance than genotypic testing. Also, unlike genotypic testing, phenotypic testing does not require a high viral load but it is recommended that persons already be taking **antiretroviral drugs**. The cost is between $700 and $900 and is now covered by many insurance plans.

AIDS serology in children

Children born to HIV-infected mothers may acquire the infection through the mother's placenta or during the birth process. Public health experts recommend the testing and monitoring of all children born to mothers with HIV. Diagnostic testing in children older than 18 months is similar to adult testing, with ELISA screening confirmed by Western blot. Younger infants can be diagnosed by direct culture of the HIV virus, PCR testing, and p24 antigen testing. These techniques allow a pediatrician to identify 50% of infected children at or near birth, and 95% of cases in infants 3–6 months of age.

Preparation

Preparation and aftercare are important parts of AIDS diagnostic testing. Doctors are now advised to take the patient's emotional, social, economic, and other circumstances into account and to provide counseling before and after testing. Patients are generally better able to cope with the results when the doctor has spent some time with them before the blood test explaining the basic facts about HIV infection and testing. Many doctors now offer this type of informational counseling before performing the tests.

Aftercare

If the test results indicate that the patient is HIV-positive, he or she will need counseling, information, referral for treatment, and support. Doctors can either counsel the patient themselves or invite an experienced HIV counselor to discuss the results of the blood tests with the patient. They also will assess the patient's emotional and psychological status, including the possibility of violent behavior and the availability of a support network.

Risks

The risks of AIDS testing are primarily related to disclosure of the patient's HIV status rather than to any physical risks connected with blood testing. Some patients are better prepared to cope with a positive diagnosis than others, depending on their age, sex, health, resources, belief system, and similar factors.

Results

Normal results for ELISA, Western blot, IFA, and PCR testing are negative for HIV antibody.

Normal results for blood cell counts:

- WBC differential: Total lymphocytes 24–44% of the white blood cells
- Hematocrit: 40–54% in men; 37–47% in women
- T cell lymphocytes: 644–2200/mm^3, 60–88% of all lymphocytes
- B cell lymphocytes: 82–392/mm^3, 3–20% of all lymphocytes
- CD4+ lymphocytes: 500–1200/mm^3, 34–67% of all lymphocytes

Abnormal results

The following results in AIDS tests indicate progression of the disease:

- Percentage of CD4+ lymphocytes: less than 20% of all lymphocytes
- CD4+ lymphocyte count: less than 200 cells/mm^3
- Viral load test: Levels higher than 5000 copies/mL
- Beta$_2$-microglobulin: Levels more than 3.5 mg/dL
- P24 antigen: Measurable amounts in blood serum

HIV infection *see* **AIDS**

Hives

Definition

Hives are due to an allergic skin reaction and cause localized redness, swelling, and **itching**.

Description

Hives are a reaction of the body's immune system that causes areas of the skin to swell, itch, and become reddened (wheals). When the reaction is limited to small areas of the skin, it is called "urticaria." Involvement of larger areas, such as whole sections of a limb, is called "angioedema." Hives can be round or they can form rings or large patches. Hives can also form wheals or welts, which are red lesions with a red flare at the borders.

Demographics

It is estimated that 5% of all people will develop urticaria at some point in their lives. Hives are more common in women than in men. Of those with chronic hives, lasting six weeks or more, about 80% are idiopathic, meaning no cause, allergic or otherwise, can be found.

Hives on the back of a young woman's legs. The accompanying inflammation develops as an allergic reaction which ranges in size from small spots to patches measuring several inches across. *(Custom Medical Stock Photo, Inc.)*

Causes and symptoms

Causes

Hives occur due to an allergic reaction. The body's immune system is normally responsible for protection from foreign invaders. When it becomes sensitized to normally harmless substances, the resulting reaction is called an allergy. An attack of hives is set off when such a substance, called an allergen, is ingested, inhaled, or otherwise contacted. The allergen interacts with immune cells called mast cells, which reside in the skin, airways, and digestive system. When mast cells encounter an allergen, they release histamine and other chemicals, both locally and into the bloodstream. These chemicals cause blood vessels to become more porous, allowing fluid to accumulate in tissue and leading to the swollen and reddish appearance of hives. Some of the chemicals released sensitize **pain** nerve endings, causing the affected area to become itchy and sensitive.

A wide variety of substances may cause hives in sensitive people, including foods, drugs, and insect bites or stings. Common culprits include:

- nuts, especially peanuts, walnuts, and Brazil nuts
- fish, mollusks, and shellfish
- eggs

- wheat
- milk
- strawberries
- food additives and preservatives
- penicillin or other antibiotics
- flu vaccines
- tetanus toxoid vaccine
- gamma globulin
- bee, wasp, and hornet stings
- bites of mosquitoes, fleas, and scabies

Symptoms

Urticaria is characterized by redness, swelling, and itching of small areas of the skin. These patches usually grow and recede in less than a day, but may be replaced by hives in other locations. Angioedema is characterized by more diffuse swelling. Swelling of the airways may cause **wheezing** and respiratory distress. In severe cases, airway obstruction may occur.

Diagnosis

Hives are easily diagnosed by visual inspection. The cause of hives is usually apparent, but may require a careful medical history in some cases.

Treatment

Mild cases of hives are treated with **antihistamines**, such as asdiphenhydramine (Benadryl) or desloratadine (Clarinex). Clarinex is non-sedating, meaning it will not make patients drowsy. More severe cases may require oral **corticosteroids**, such as prednisone. Topical corticosteroids are not effective. Airway swelling may require emergency injection of epinephrine (adrenaline).

Alternatives

An alternative practitioner will try to determine what allergic substance is causing the reaction and help the patient eliminate or minimize its effects.To deal with the symptoms of hives, an oatmeal bath may help to relieve itching. Chickweed (*Stellaria media*), applied as a poultice (crushed or chopped herbs applied directly to the skin) or added to bath water, may also help relieve itching. Several homeopathic remedies, including *Urtica urens* and *Apis* (*Apis mellifica*), may help relieve the itch, redness, or swelling associated with hives.

Prognosis

Most cases of hives clear up within 1–7 days without treatment, providing the cause (allergen) is found and avoided.

Prevention

Preventing hives depends on avoiding the allergen causing them. Analysis of new items in the diet or new drugs taken may reveal the likely source of their action. Chronic hives may be aggravated by **stress**, **caffeine**, alcohol, or tobacco; avoiding these may reduce the frequency of reactions.

Hodgkin's lymphoma

Definition

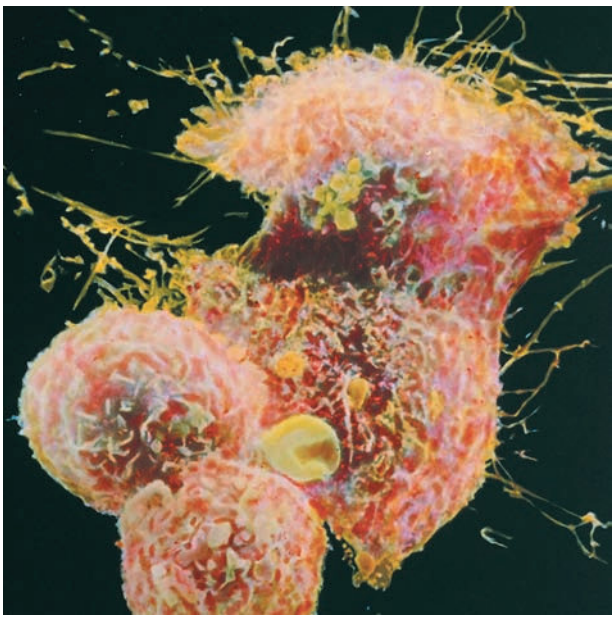
Hodgkin's lymphoma is a rare lymphoma, a cancer of the lymphatic system.

Demographics

The American Cancer Society estimated 8,510 new cases of Hodgkin's lymphoma in the United States in 2009—3,870 in females and 4,640 in males. It is estimated that 800 men and 490 women in the United States died of the disease in 2009.

Hodgkin's lymphoma can occur at any age. However, the majority of cases develop in early adulthood (ages 15–40) and late adulthood (after age 55).

WWW.BOOKBAZ.IR



A scanning electron micrograph (SEM) image of dividing Hodgkin's cells from the pleural effusions (abnormal accumulations of fluid in the lungs) of a 55-year-old male patient. *(Dr. Andrejs Liepins/Photo Researchers, Inc.)*

Approximately 10–15% of cases are in children under age 17. It is more common in boys than in girls under the age of 10. The disease is very rare in children under age five.

Description

Hodgkin's lymphoma, or Hodgkin's disease, was first described in 1832 by British physician Thomas Hodgkin's. Hodgkin's clearly differentiated between this disease and the much more common non-Hodgkin's lymphomas. Prior to 1970, few individuals survived Hodgkin's lymphoma. Due to significant treatment advancements, the majority of individuals with this cancer can be cured.

The lymphatic system is part of the body's immune system, for fighting disease, and a part of the blood-producing system. It includes the lymph vessels and nodes, the spleen, bone marrow, and thymus. The narrow lymphatic vessels carry lymphatic fluid throughout the body. The lymph nodes are small organs that filter the lymphatic fluid and trap foreign substances, including viruses, bacteria, and cancer cells. The spleen, in the upper left abdomen, removes old cells and debris from the blood. The bone marrow, the tissue inside the bones, produces new red and white blood cells.

Lymphocytes are white blood cells that recognize and destroy disease-causing organisms. Lymphocytes are produced in the lymph nodes, spleen, and bone marrow. They circulate throughout the body in the blood and lymphatic fluid. Clusters of immune cells also exist in major organs.

Hodgkin's lymphoma is a type of lymphoma in which antibody-producing cells of the lymphatic system begin to grow abnormally. It usually begins in a lymph node and progresses slowly, in a fairly predictable way, spreading via the lymphatic vessels from one group of lymph nodes to the next. Sometimes it invades organs that are adjacent to the lymph nodes. If the cancer cells spread to the blood, the disease can reach almost any site in the body. Advanced cases of Hodgkin's lymphoma may involve the spleen, liver, bone marrow, and lungs.

There are different subtypes of Hodgkin's lymphoma:

- nodular sclerosis (60–80% of cases); most common subtype affecting younger patients
- mixed cellularity (15–30% of cases) most common subtypes in patients diagnosed after age 55
- lymphocyte predominant or lymphocyte rich (5% of cases)
- lymphocyte depleted (less than 1% of cases)

These four subtypes are referred to as classic Hodgkin's lymphoma. A fifth subtype, nodular lymphocyte predominant Hodgkin's lymphoma (NLPHD), which accounts for about 5% of cases, is a subtype that is clinically unique from the other subtypes and is treated differently.

Risk factors

Although the exact cause of Hodgkin's lymphoma is not yet known, several risk factors related to the disease have been identified including:

- Previous infection with the Epstein Barr virus/infectious mononucleosis (mono). The overall risk of developing Hodgkin's lymphoma after this infection is small. According to a study conducted in Denmark and Sweden, the average time between illness with infectious mononucleosis and diagnosis of Hodgkin's lymphoma was about three years.
- Age—Individuals in their twenties and adults over the age of 55 are more likely to be diagnosed with Hodgkin's lymphoma.
- Gender—Males are more likely to be diagnosed with this type of lymphoma. In children, up to 85% of cases are diagnosed in boys.
- Family history—Siblings of patients who have been diagnosed with Hodgkin's lymphoma are at higher risk than the general population. An identical twin of an individual who has been diagnosed with

KEY TERMS

Excisional biopsy—Removal of an entire lymph node; often the most suspicious-looking node is removed for testing.

Incisional biopsy—Removal of a part of a lymph node for diagnostic purposes.

Lymph node—Small, round-shaped organs of the lymph system found throughout the body that are connected by lymph vessels.

Lymphatic system—A system of the body that includes lymph vessels and nodes, the spleen, bone marrow, and the thymus.

Lymphoma—Cancer originating in a lymph node or in the lymph system.

Reed-Sternberg cells—Cancerous cells that, when present in the body, are indicative of Hodgkin's lymphoma.

Hodgkin's is at even higher risk. However, less than 5% of cases are diagnosed in family members.

- Patients with human immunodeficiency virus (HIV) infection are more likely to develop Hodgkin's lymphoma than those not diagnosed with HIV.

Causes and symptoms

The cause of Hodgkin's lymphoma is not known. It is suspected that some interaction between an individual's genetic makeup, environmental exposures, and infectious agents may be responsible. Immune system deficiencies may be involved.

Early symptoms of Hodgkin's lymphoma are similar to those of the flu:

- fevers, night sweats, chills
- fatigue
- itching
- swelling of one or more lymph nodes
- loss of appetite
- weight loss
- pain after drinking alcoholic beverages (occurs in less than 10% of patients)

Sudden or emergency symptoms of Hodgkin's lymphoma include:

- sudden high fever
- loss of bladder and/or bowel control
- numbness in the arms and legs and a loss of strength

As lymph nodes swell, they may push on other structures, causing a variety of symptoms:

- pain due to pressure on nerve roots
- loss of function in muscle groups served by compressed nerves
- coughing or shortness of breath due to compression of the windpipe and/or airways by swollen lymph nodes in the chest
- kidney failure from compression of the ureters, the tubes that carry urine from the kidneys to the bladder
- swelling in the face, neck, or legs, due to pressure on veins
- paralysis in the legs due to pressure on the spinal cord

As Hodgkin's lymphoma progresses, the immune system becomes less effective at fighting infection. Thus, patients with Hodgkin's lymphoma become more susceptible to both common infections caused by bacteria and opportunistic infections.

As many as 75% of individuals with Hodgkin's lymphoma do not have any typical symptoms.

Diagnosis

As with many forms of cancer, diagnosis of Hodgkin's lymphoma has two major components.

- Identification of Hodgkin's lymphoma as the cause of the patient's disease.
- Staging of the disease to determine how far the cancer has spread.

Examination

The initial diagnosis of Hodgkin's lymphoma often results from abnormalities in a **chest x ray** that was performed because of nonspecific symptoms. The physician then takes a medical history to check for the presence of symptoms and conducts a complete **physical examination**.

The size, tenderness, firmness, and location of swollen lymph nodes are determined and correlated with any signs of infection. In particular, lymph nodes that do not shrink after treatment with **antibiotics** may be a cause for concern. The lymph nodes that are most often affected by Hodgkin's lymphoma include those of the neck, above the collarbone, under the arms, and in the chest above the diaphragm.

WWW.BOOKBAZ.IR

Tests

Laboratory tests that may be ordered as part of the diagnostic workup for Hodgkin's lymphoma include:

- Lactate dehydrogenase (LDH) level—High levels of LDH may be indicative of more extensive disease.
- Complete blood count (CBC)—Anemia may be present if there is disease in the bone marrow. The platelet count may be increased or decreased.
- Alkaline phosphatase (ALP) levels—ALP may be increased if there is disease in the liver and/or bone.
- An HIV test should be done if HIV infection is suspected. Antiviral therapies to treat HIV should be initiated because they have a positive impact in HIV-positive patients diagnosed with Hodgkin's lymphoma.

Procedures

Diagnosis of Hodgkin's lymphoma requires either the removal of an entire enlarged lymph node (an excisional biopsy) or an incisional biopsy (the recommended procedure), in which only a small part of a large tumor is removed. If the node is near the skin, the biopsy is performed with a local anesthetic. If it is inside the chest or abdomen, general **anesthesia** is required.

The sample of biopsied tissue is examined under a microscope. Giant cells called Reed-Sternberg cells must be present to confirm a diagnosis of Hodgkin's lymphoma. These cells, which usually contain two or more nuclei, are named for the two pathologists who discovered them. Normal cells have only one nucleus (the organelle within the cell that contains the genetic material). Affected lymph nodes may contain only a few Reed-Sternberg cells and they may be difficult to recognize. Characteristics of other types of cells in the biopsied tissue help to diagnose the subtype of Hodgkin's lymphoma.

A fine needle aspiration (FNA) biopsy, in which a thin needle and syringe are used to remove a small amount of fluid and bits of tissue from a tumor, has the advantage of not requiring surgery. An FNA may be performed prior to an excisional or incisional biopsy, to check for infection or for the spread of cancer from another organ. However, an FNA biopsy does not provide enough tissue to diagnose Hodgkin's lymphoma. FNA is generally indicated only when a **head and neck cancer** is suspected.

Occasionally, additional biopsies are required to diagnose Hodgkin's lymphoma. In rare instances, other tests that detect certain substances on the surfaces of cancer cells or changes in the DNA of cells are used to distinguish Hodgkin's lymphoma from non-Hodgkin's's lymphoma.

Staging is very important in Hodgkin's lymphoma. This is because the cancer usually spreads in a predictable pattern, without skipping sets of lymph nodes until late in the progression of the disease.

Tests

Imaging of the abdomen, chest, and pelvis is used to identify areas of enlarged lymph nodes and abnormalities in the spleen or other organs. Computerized axial tomography (CT or CAT) scans use a rotating x ray beam to obtain pictures. Chest x rays also may be taken. These images reveal rounded lumps called nodules in the affected lymph nodes and other organs.

Positron emission tomography (PET) scan, considered to be an essential diagnostic tool in Hodgkin's lymphoma, is an extremely accurate method for staging Hodgkin's lymphoma. A very low dose of radioactive glucose, a sugar, is injected into the body. The glucose travels to metabolically active sites, including cancerous regions that require large amounts of glucose. The PET scan detects the radioactivity and produces images of the entire body that distinguish between cancerous and non-cancerous tissues.

Anemia (a low red-blood-cell count), fevers, or night sweats are indications that Hodgkin's lymphoma may be in the bone marrow. In these cases, a bone-marrow biopsy, in which a large needle is used to remove a narrow, cylindrical piece of bone, may be necessary to determine the spread of the cancer. Alternatively, an aspiration, in which a needle is used to remove small bits of bone marrow, may be used. The marrow usually is removed from the back of the hip or other large bone.

Rarely, further staging, called pathological staging or a staging laparotomy, is used for Hodgkin's lymphoma. In this operation, a surgeon checks the abdominal lymph nodes and other organs for cancer and removes small pieces of tissue. A pathologist examines the tissue samples for Hodgkin's lymphoma cells. Usually the spleen is removed (a **splenectomy**) during the laparotomy. The splenectomy helps with staging Hodgkin's lymphoma, as well as removing a disease site. The staging laparotomy is infrequently used.

Treatment

All of the available treatments for Hodgkin's lymphoma have serious side effects, both short and long-

DOROTHY MENDENHALL (1874–1964)

Dorothy Reed Mendenhall, the last of three children, was born September 22, 1874, in Columbus, Ohio, to William Pratt Reed, a shoe manufacturer, and Grace Kimball Reed, both of whom had descended from English settlers who came to America in the seventeenth century. Mendenhall attended Smith College and obtained a baccalaureate degree. Although she initially contemplated a career in journalism, Mendenhall's interest in medicine was inspired by a biology course she attended.

Dorothy Reed Mendenhall was a well-respected researcher, obstetrician, and pioneer in methods of childbirth. She was the first to discover that Hodgkin's lymphoma was not a form of tuberculosis, as had been thought. This finding received international acclaim. As a result of her work, the cell type characteristic of Hodgkin's lymphoma bears her name. The loss of her first child due to poor obstetrics changed her research career to a lifelong effort to reduce infant mortality rates. Mendenhall's efforts paid off with standards being set for weight and height for children ages birth to six and also in programs that stressed the health of both the mother and child in the birthing process.

term. Goals of treatment include minimizing treatment for patients who have been diagnosed with low-risk disease in early stages. With accurate staging, physicians and patients often can choose the minimum treatment that will cure the disease. The staging system used most often to stage Hodgkin's lymphoma is the Ann Arbor Staging Classification System.

Hodgkin's lymphoma is divided into four stages, with additional substages:

- Stage I: The disease is confined to one lymph node area or to one site outside of a lymph node.
- Stage II: The disease is in two or more lymph node areas on one side of the diaphragm (the muscle below the lungs).
- Stage III: The disease is in lymph node areas on both sides of the diaphragm.
- Stage IV: The disease has spread from the lymphatic system to one or more other organs, such as the bone marrow or liver.

Treatment for Hodgkin's lymphoma depends both on the stage of the disease and whether or not symptoms are present. Stages are labeled with an A if no symptoms are present. If symptoms are present, the stage is labeled with a B. These symptoms include:

- unexplained or unintended loss of more than 10% of body weight over the previous six months
- fevers above 100°F (37.7°C)
- drenching night sweats

Drugs

Combined modality treatment incorporating **radiation therapy** and/or **chemotherapy** (drug therapy) are the standard treatments for Hodgkin's lymphoma. If the disease is confined to one area of the body, radiotherapy is usually used. This treatment, with x rays or other high-energy rays, is used when the disease is in bulky areas such as the chest, where chemotherapeutic drugs cannot reach all of the cancer. External-beam radiation, a focused beam from an external machine, is used to irradiate only the affected lymph nodes. This procedure is called involved field radiation. Chemotherapy is also used to treat early stage disease to enhance the effects of the radiation therapy; this is called a synergistic effect.

Involved field radiation may also be used in patients with advanced disease who have disease remaining after treatment with chemotherapy.

Since external-beam radiation damages healthy tissue near the cancer cells, the temporary side effects of radiotherapy can include sunburn-like skin damage, **fatigue**, nausea, and **diarrhea**. Other temporary side effects may include a **sore throat** and difficulty swallowing. Long-term side effects depend on the dose and the location of the radiation and the age of the patient. Since radiation of the ovaries causes permanent sterility (the inability to have offspring), the ovaries of girls and young women are protected during radiotherapy. Sometimes the ovaries are surgically moved from the region to be irradiated. The testes should also be shielded if they are in a radiation field.

Chemotherapy utilizes a combination of drugs, each of which kills cancer cells in a different way. The most common chemotherapy regimens for Hodgkin's lymphoma are MOPP (either mechlorethamine or methotrexate with oncovin, procarbazine, and prednisone) and ABVD (adriamycin or doxorubicin, bleomycin, vincristine, dacarbazine). Each of these consists of four different drugs. ABVD, now considered the standard regimen to treat Hodgkin's lymphoma, is used more frequently than MOPP because it has fewer severe side effects such as sterility and because ABVD has been proven to be superior in terms of outcomes. Use of ABVD also reduces the risk of development of a secondary leukemia. MOPP may be used for individuals who are at risk for **heart**

WWW.BOOKBAZ.IR

failure. The chemotherapeutic drugs may be injected into a vein or taken orally (prednisone).

Children who are sexually mature when they develop Hodgkin's lymphoma, and whose muscle and bone mass are almost completely developed, usually receive the same treatment as adults. Younger children usually are treated with chemotherapy, since radiation will adversely affect bone and muscle growth. However, radiation may be used in low dosages in combination with chemotherapy. Chemotherapy for children with Hodgkin's lymphoma usually includes more drugs than ABVD and MOPP.

The side effects of chemotherapy for Hodgkin's lymphoma depend on the dose of drugs and the length of time they are taken. Since these drugs target rapidly dividing cancer cells, they also affect normal cells that grow rapidly. These include the cells of the bone marrow, the linings of the mouth and intestines, and hair follicles. Damage to bone marrow leads to lower white blood cell counts and lower resistance to infection. It also leads to lower red blood cell counts, which can result in fatigue and easy bleeding and bruising. Damage to intestinal cells leads to a loss of appetite, nausea, and **vomiting**. Mouth sores and hair loss also are common side effects of chemotherapy. These side effects disappear when the chemotherapy is discontinued. Some drugs can reduce or prevent the **nausea and vomiting**.

Chemotherapy for Hodgkin's lymphoma may lead to long-term complications. The drugs may damage the heart, lungs, kidneys, and liver. In children, growth may be impeded. Some chemotherapy can cause sterility, so men may choose to have their sperm frozen prior to treatment. Women may stop ovulating and menstruating during chemotherapy. This may or may not be permanent.

The development of a second type of cancer is the most serious risk from radiation and chemotherapy treatment for Hodgkin's lymphoma. In particular, there is a risk of developing leukemia, **breast cancer**, **bone cancer**, or **thyroid cancer**. Chemotherapy, particularly MOPP, or chemotherapy in conjunction with radiotherapy, significantly increases the risk for leukemia.

Following treatment, the original diagnostic tests for Hodgkin's lymphoma are repeated, to determine whether all traces of the cancer have been eliminated and to check for long-term side effects of treatment. In resistant Hodgkin's lymphoma, some cancer cells remain following treatment. If the cancer continues to spread during treatment, it is called progressive Hodgkin's lymphoma. If the disease returns after treatment, it is known as recurrent Hodgkin's lymphoma. It may recur in the area where it first started or elsewhere in the body. It may recur immediately after treatment or many years later.

Additional treatment is necessary with these types of Hodgkin's lymphoma. Salvage therapy for refractory or recurrent Hodgkin's lymphoma includes the chemotherapy regimens ICE (ifosfamide, mesna, carboplatin, and etoposide), the DHAP regimen (cisplatin, cytarabine, and dexamethasone), and the EPOCH regimen (etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone).

An autologous bone marrow and/or a peripheral blood **stem cell transplantation** (PBSCT) often is recommended for treating resistant or recurrent Hodgkin's lymphoma, particularly if the disease recurs within a few months of a chemotherapy-induced remission. These transplants are autologous because they utilize the individual's own cells. The patient's bone marrow cells or peripheral blood stem cells (immature bone marrow cells found in the blood) are collected and frozen prior to high-dosage chemotherapy, which destroys bone marrow cells. A procedure called leukapheresis is used to collect the stem cells. Following the high-dosage chemotherapy, and possibly radiation, the bone marrow cells or stem cells are reinjected into the individual.

Most complementary therapies for Hodgkin's lymphoma are designed to stimulate the immune system to destroy cancer cells and repair normal cells that have been damaged by treatment. These therapies are used in conjunction with standard treatment.

Targeted **immunologic therapies**, also known as immunotherapies, biological therapies, or biological response modifier therapies, utilize substances that are produced by the immune system. These include interferon (an immune system protein), **monoclonal antibodies** (specially engineered antibodies), colony-stimulating (growth) factors (such as filgrastim), and vaccines. Many immunotherapies for Hodgkin's lymphoma are being evaluated and most are available only through clinical trials. As of 2014, targeted immunotherapy agents have shown modest effects when used to treat refractory or recurrent Hodgkin's lymphoma.

Prognosis

Hodgkin's lymphoma, particularly in children, is one of the most curable forms of cancer. Approximately 90% of individuals are cured of the disease with chemotherapy and/or radiation.

The one-year relative survival rate following treatment for Hodgkin's lymphoma is 93%. Relative survival rates do not include individuals who die of causes other than Hodgkin's lymphoma. The percentage of individuals who have not died of Hodgkin's lymphoma within five years of diagnosis is 90–95% for those with stage I or stage II disease. The figure is 85–90% for those diagnosed with stage III Hodgkin's lymphoma and approximately 65% for those diagnosed with stage IV disease. The 15-year relative survival rate is 63%. Approximately 75% of children are alive and cancer free 20 years after the original diagnosis of Hodgkin's lymphoma.

Acute myelocytic leukemia, a very serious cancer, may develop in as many as 2–6% of individuals receiving certain types of treatment for Hodgkin's lymphoma. Women under the age of 30 who are treated with radiation to the chest have a much higher risk for developing breast cancer. Both men and women are at higher risk for developing lung or thyroid cancers as a result of chest irradiation.

Individuals with the type of Hodgkin's lymphoma known as nodular lymphocytic predominance have a 2% chance of developing non-Hodgkin's lymphoma. This appears to be a result of the Hodgkin's lymphoma itself and not the treatment.

Prevention

As it is not known exactly what causes Hodgkin's lymphoma, it is not possible to prevent the occurrence of this type of cancer.

Most relapses of disease after treatment with Hodgkin's lymphoma occur within the first three years after treatment has been completed. Therefore, compliance with scheduled follow-up visits is extremely important. A typical schedule for follow-up after completion of treatment of Hodgkin's lymphoma is as follows:

- every 2–4 months during the first two years
- every 3–6 months during the next 3–5 years

Holistic medicine

Definition

Holistic medicine is a form of health care that considers and treats the entire person who is ill, in distinction to treating the specific disease or medical condition.

Description

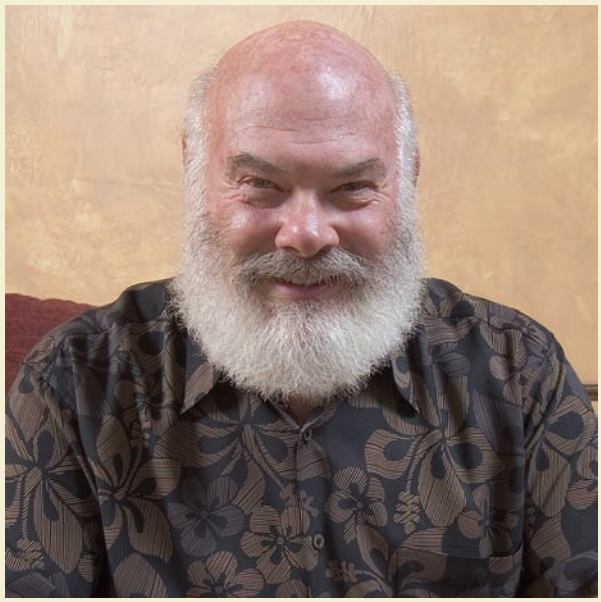
Practitioners of holistic medicine attempt to address patients' physical, spiritual, and emotional needs, believing that these aspects may be causes or contributors to illness. The primary goal of the practice of holistic medicine is to get the physical, spiritual, emotional, and cognitive aspects of the patient in balance, for it is believed that without this equilibrium, complete health cannot be achieved.

Treatment in holistic medicine may include the use of conventional medicine, but it also encompasses alternative treatment modalities. Massage and relaxation exercises in many forms are often employed, but the most common alternative treatments are:

- Traditional Chinese medicine. Traditional Chinese medicine is based on the concept of the *Qi,* considered a vital energy force that is believed to flow in

WWW.BOOKBAZ.IR

ANDREW WEIL (1942–)



(AP Images.)

Dr. Andrew Weil, a Harvard-educated physician, adds credibility and expertise to the natural healing methods he espouses in his best-selling books, on his Internet Web site, in his talk show appearances, and in his popular audio CD of music and meditation. Weil's *Spontaneous Healing* spent more than a year on the best-seller list, and his 1997 book, *Eight Weeks to Optimum Health*, also was a runaway best-seller. Perhaps the best-known proponent of naturalistic healing methods, Weil has been trying to establish a field he calls integrative medicine. He is director of Tucson's Center for Integrative Medicine, which he founded in 1993. In 1997, he began training doctors in the discipline at the University of Arizona, where he teaches.

After getting his bachelor's degree in botany from Harvard University, Weil applied for admission to Harvard Medical School in 1964. During his second year, he led a group of students who argued they could succeed better studying on their own than going to classes; in fact, the group got higher scores on their final exams than their classmates. After graduating from Harvard Medical School, he volunteered at the notorious counter- cultural Haight-Asbury Free Clinic in San Francisco, CA. Later in 1969, Weil got a job in Washington, DC, with the National Institute of Mental Health's Drug Studies Division. From 1971 to 1975, he traveled extensively in South America and Africa, soaking up information about medicinal plants, shamanism, and natural healing techniques. He never returned to the practice of conventional medicine.

His approach to alternative medicine is eclectic, mingling traditional medicine with herbal therapy, acupuncture, homeopathy, chiropractic, hypnotism, cranial manipulation, and other alternative healing methods. Though his books discuss the benefits of everything from healing touch to herbal cures, Weil does not dismiss the benefits of standard Western medicine when appropriate. His philsophies, methods and products can be found by visiting http://www.drweil.com/.

specific paths throughout the body. Diagnosis is made from examination of the tongue and/or pulse of the radial artery, which are thought to reflect disorders in the organs of the body. Treatment is given with herbal medicines.

- Acupuncture. Acupuncture is a form of traditional Chinese medicine that taps into the qi by inserting needles into specific paths called meridians. The qi is thought to flow without interruption in health and become blocked in disease. The needles are thought to unblock the obstruction and restore free flow of the qi.
- Ayurvedic medicine. Ayurvedic, or Indian, medicine has strong links with Buddhism and Hinduism. It is based on the idea that health is controlled by three "humors," and that illness or disease is the result of imbalance in these humors. Treatments are mainly based on plant materials. Some of the plant medicines, however, have been found to contain high levels of metals such as lead, mercury, or arsenic, which can negatively affect health.
- Homeopathy. Homeopathy is a treatment modality that is based on the belief that extremely small toxins can treat symptoms caused by large doses of the toxins. The medicines are extremely diluted and are believed to be effective because they mimic or contain the essence or "fingerprint" of the compound causing the ailment.
- Naturopathy. Naturopathy is based on the belief that a vital energy force governs the physiology of the body's organs. Practitioners use naturally occurring substances, minimally invasive methods, and healthy diet and exercise to encourage natural healing. Use of pharmaceuticals and surgery are generally not encouraged.
- Diet and herbal remedies. Diet and herbal remedies have been used since ancient times for medicinal purposes. In fact, many certain plants and fungi contain chemicals that are used in standard medicine. The therapeutic use of diet and herbal remedies are widespread practices in non-industrialized

societies and in Asian countries. Some herbs can be used as metabolites, antimicrobial salves, and skin balms. Familiar herbal products such as opium, aspirin, digitalis, and quinine are used in medicine today for pain control, heart medication, and the control of lupus, arthritis, and nocturnal leg cramps.

- Biofield therapies. Biofield therapies involve the use of crystals, magnets, or electronic fields to influence the so-called "energy fields" in the body.

It should be noted that the drugs, herbs, and other substances used in complementary medicine are for the most part not regulated and not tested by government agencies in the United States and abroad. Also, not all practitioners of holistic or complementary medicine are licensed or recognized by state health boards or health insurance companies.

In holistic medical practice, standard medicine is viewed as a complement to treatment, in the same way as any alternative treatment might be. Thus, in this framework, it is incorrect to characterize holistic medicine as "alternative" or "complementary" medicine. Its practitioners argue that holistic medicine is a more encompassing treatment regime than any of the others taken singly, though it often uses conventional medicine as one of the treatment modalities.

Because holistic medicine views conventional or standard medical practice as one treatment option among various choices, it is not warmly received by many in the medical community who argue that holistic medicine is not a safe and proven adjunct to established medical treatment. Thus, the terms "alternative," "complementary," and "integrative" medicine are controversial and are far from accepted by mainstream medical science. Many feel that the terms "complementary" and "integrative" misleadingly suggest that unsubstantiated, ethereal energies often associated with holistic therapies can improve science-based treatment. Moreover, labeling standard medical practice as "conventional" erroneously implies that holistic therapies share equal scientific validity and proven credibility with mainstream medicine, and that the "alternative" treatment is merely less well known.

A major criticism brought against holistic medicine is the lack of scientific evidence in peer-reviewed journals to support the efficacy of its treatments. Others note that research on holistic medicine is lacking mainly as a matter of economics: Large pharmaceutical companies with financial wherewithal can fund numerous major research projects, whereas holistic practice does not have that kind of financial pull and the result is fewer studies on its effectiveness. In addition, many medical scientists argue that any positive results obtained from holistic medicine can be attributed to the placebo effect. In other words, the patient's faith in the treatment determines his or her sense of its efficacy.

Nonetheless, research on holistic medicine is conducted, and some studies show positive results. For instance, a 2013 study demonstrated that **yoga** and meditation-based therapies may help people quit **smoking**. The study, which reviewed 14 clinical trials, found that all 14 trials reported positive results, such as ability to quit, reductions in number of cigarettes smokes per day, and reductions in cravings.

The negative view of holistic medicine may be changing. Integrative Fellowships are now available to physicians at some of the major medical centers and medical schools. These programs provide physicians with the opportunity to learn about methods for combining complementary health care services into their medical practices. This has been evidenced in **palliative care**, where complementary medicine has been shown to be useful.

Holter monitoring

Definition

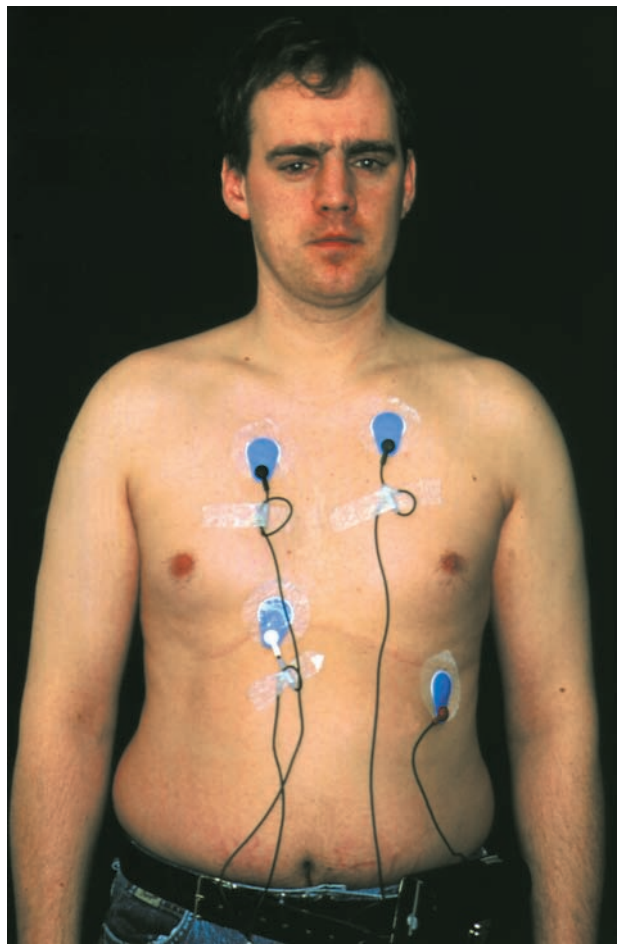
Holter monitoring is continuous monitoring of the electrical activity of a patient's heart muscle (**electrocardiography**) for 24 hours, using a special portable device called a Holter monitor. Patients wear the Holter monitor while carrying out their usual daily activities.

Purpose

Holter monitoring is used to help determine whether someone has an otherwise undetected **heart disease**, such as abnormal heart rhythm (cardiac arrhythmia), or inadequate blood flow through the heart. Specifically, it can detect abnormal electrical activity in the heart that may occur randomly or only under certain circumstances, such as during sleep or periods of physical activity or **stress**, which may or may not be picked up by standard, short-term electrocardiography performed in a doctor's office.

Traditionally, an **exercise stress test** has been used to screen people for "silent" heart disease (heart disease with none of the usual symptoms). However, an exercise stress test is not completely foolproof, often producing false negative results (indicating no heart disease when heart disease is actually present) and false positives (indicating heart disease when there is none). Furthermore, some people cannot undergo exercise stress testing because of other medical conditions, such as arthritis.

Holter monitoring, also known as ambulatory or 24-hour electrocardiography, offers an alternate means of testing people for heart disease. By monitoring electrocardiographic activity throughout the day, Holter monitoring can uncover heart problems that occur during the patient's everyday activities. It can also help to recognize any activities that may be causing the heart problems. It can define and correlate symptoms that may be caused by irregularities of the heart.



A male patient wears electrodes attached to his chest, which is connected to a Holter monitor at his waist. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

Precautions

Holter monitoring is an extremely safe procedure and no special precautions are required.

Description

The technician affixes electrodes on the surface of the skin at specific areas of the patient's chest, using adhesive patches with special gel that conducts electrical impulses. Typically, electrodes are placed under each collarbone and each bottom rib, and several electrodes are placed across the chest in a rough outline of the heart. The electrodes are attached to a portable electrocardiographic device called a Holter monitor, which records the electrical activity of the heart over 24–48

hours. The device is worn over the patient's shoulder or attached to a belt around the waist.

The Holter monitor records the continuous electrical activity throughout the course of the day, while the patient carries out his or her daily activities. During this time, the patient also keeps a detailed log or diary, recording his or her various activities, such as exercise, eating, sleeping, straining, breathing too hard (hyperventilating), and any stressful situations. The patient also notes the time and circumstances of any symptoms—especially chest **pain**, **dizziness**, **shortness of breath**, heart **palpitations**, and any other signs of heart trouble. Some Holter monitors allow patients to record their symptoms electronically, highlighting the portion of the electrocardiogram recorded while the symptoms are occurring.

After 24–48 hours, the Holter monitor is removed. A computer-assisted analysis is performed on the electrocardiographic recording, and the doctor compares the recording against the patient's log to see if there is any correlation between electrocardiographic abnormalities and any of the patient's activities or symptoms. The physician makes a final interpretation.

Preparation

In the doctor's office, electrodes are attached to the patient's chest. In some cases, the patient's chest hair may have to be shaved to facilitate attaching the electrodes. The patient then begins carrying the monitor on a shoulder harness, in a pocket, or on the belt while carrying out his or her usual daily routine. The patient should inform the doctor of any drugs he or she may be taking, because certain drugs can alter heart rhythms and may affect the results of the test.

Aftercare

The patient returns to the doctor's office to have the monitor and electrodes removed. No special measures need to be taken following Holter monitoring. The test results are usually available within a few days after the monitor is removed.

Risks

There are no known risks associated with Holter monitoring. The main complaint that people have with Holter monitoring is that the monitor may be cumbersome and interfere with certain activities, especially sleeping. Bathing and showering are not allowed during the study.

Results

A normal Holter monitoring test shows relatively normal electrical activity in the heart around the clock and no evidence of silent ischemia (deprivation of oxygen-rich blood).

Abnormal results

An abnormal result on Holter monitoring may indicate ischemia to the heart muscle or heart rhythm disturbances. Abnormalities are especially likely to show up during periods of stress or heavy activity, but sometimes serious abnormalities are recorded while the patient is sleeping.

Holtzman ink blot test

Definition

The Holtzman Inkblot Technique (HIT) is a projective personality assessment test for persons ages five and up.

Purpose

The HIT is used to assess the personality structure of a test subject. It is sometimes used as a diagnostic tool in assessing **schizophrenia**, depression, **addiction**, and character disorders.

Precautions

Psychometric testing requires a clinically trained examiner. The HIT should be administered and interpreted by a trained psychologist, psychiatrist, or appropriately trained mental health professional.

Some consider projective tests to be less reliable than objective personality tests. If the examiner is not well-trained in psychometric evaluation, subjective interpretations may affect the outcome of the test.

WWW.BOOKBAZ.IR

Description

The HIT, developed by psychologist Wayne Holtzman and colleagues, was introduced in 1961. The test was designed to overcome some of the deficiencies of its famous predecessor, the Rorschach Inkblot Test.

Unlike the Rorschach, the Holtzman is a standardized measurement with clearly defined objective scoring criteria. The HIT consists of 45 inkblots. The test administrator, or examiner, has a stack of 47 cards with inkblots (45 test cards and 2 practice cards) face down in front of him or her. The examiner hands each card to the subject and asks the test subject what he or she sees in the inkblot. Only one response per inkblot is requested. Occasionally, the examiner may ask the test subject to clarify or elaborate on a response. The administration of the HIT typically takes 50–80 minutes. The HIT is then scored against 22 personality-related characteristics.

The HIT can also be administered in a group setting. In group testing, 30–45 inkblots are projected onto a screen and test subjects provide written responses to each inkblot.

Medicare reimbursement rates for psychological and **neuropsychological testing** is $58.35 an hour. Billing time typically includes test administration, scoring and interpretation, and reporting. Many insurance plans cover all or a portion of diagnostic psychological testing.

Results

Because of the complexity of the scoring process and the projective nature of the test, results for the HIT should only be interpreted by a clinically trained psychologist, psychiatrist, or appropriately trained mental health professional.

Home care

Definition

Home care is a form of skilled health care service provided where a patient lives. It is sometimes called domiciliary care. Patients can receive home care services whether they live in their own homes, with or without family members, or in an assisted living facility. According to the National Center for Health Statistics (NCHS), about 1.5 million persons in the United States receive home care.

Description

The goal of home care is to allow the patient to remain living at home, regardless of age or disability. After surgery, a patient may require home care services that may range from such homemaking services as cooking or cleaning to skilled medical care. In the United States, most home care (about 80%) is still provided by members of patients' families; however, some patients also require home health aides or personal care attendants to help them with activities of daily living (ADLs), which are usually defined as activities necessary for adequate self-care, such as bathing, dressing, going to the toilet, and the like. A second category, instrumental activities of daily living (IADLs), refers to tasks that a person must be capable of carrying out in order to live independently. IADLs include being able to perform light housework, prepare meals, take medications, go shopping for groceries or clothes, use the telephone, and manage money.

Medical, dental, and nursing care may all be delivered in patients' homes, which allows them to feel more comfortable and less anxious. The professionals most often involved in home care in the United States are nurses, followed by physical therapists and home health aides. Therapists from speech-language pathology, **physical therapy**, and **respiratory therapy** departments often make regular home visits, depending on a patient's specific needs. General nursing care is provided by both registered and licensed practical nurses; however, there are also nurses who are clinical specialists in psychiatry, obstetrics, and cardiology who may provide care when necessary. Home health aides provide what is called custodial care in domestic settings; their duties are similar to those of nurses' aides in the hospital. Professionals who deliver care to patients in their homes are employed either by independent for-profit home-care agencies, hospital agencies, or hospital departments. Personal care attendants can also be hired privately by patients; however, not only is it more difficult to evaluate an employee's specific background and credentials when he or she is not associated with a certified agency or hospital, but medical insurance may not cover the expense of an employee who does not come from an approved source.

KEY TERMS

Activities of daily living (ADLs)—Self-care activities performed during the course of a normal day such as eating, bathing, dressing, toileting, etc.

Home health aide—An employee of a home care agency who provides the same services to a patient in the home as nurses' aides perform in hospitals and nursing homes.

Instrumental activities of daily living (IADLs)—Daily tasks that enable a person to live independently.

Licensed practical nurse (LPN)—A person who is licensed to provide basic nursing care under the supervision of a physician or a registered nurse.

Medicaid—The federally funded program in the United States for state-operated programs that provide medical assistance to permanently disabled patients and to low-income people. Medicaid is the medical assistance provided in Title XIX of the Social Security Act.

Medicare—The federally funded national health insurance program, provided for by Title XVIII of the Social Security Act in the United States for all people over the age of 65.

Personal care attendant—An employee hired either through a healthcare facility, home care agency, or private agency to assist a patient in performing ADLs.

Psychiatric nursing—The nursing specialty concerned with the prevention and treatment of mental disorders and their consequences.

Registered nurse—A graduate nurse who has passed a state nursing board examination and has been registered and licensed to practice nursing.

Respiratory therapy—The department of any health care facility or agency that provides treatment to patients to maintain or improve their breathing function.

Speech-language pathology—Formerly known as speech therapy, it includes the study and treatment of human communication—its development and disorders.

Home care nurses provide care for patients of every age, economic class, and level of disability. Some nurses provide specialized hospice, mental health, or pediatric care. Home care nursing often involves more than biomedical-based care, depending on a patient's religious or spiritual background.

The NCHS reported that 76% of the 1.5 million persons receiving home care in the United States lived with a primary caregiver, usually a spouse, adult son or daughter, another relative, or a parent (in that order). Of adults aged 65, 6–7% needed assistance with ADLs, compared to 20.6% of persons over 85. Women were more likely to need assistance with ADLs than men. With regard to payment, 710,000 persons paid through Medicare and 277,000 through Medicaid.

Viewpoints

Most patients are more comfortable in their own homes than in a hospital setting. Consequently, home care continues to grow in popularity. Depending on the patient's living status and relationships with others in the home, however, the home is not always the best place for caregiving. Hospital stays have been shortened considerably, starting in the 1980s with the advent of the diagnosis-related group (DRG) reimbursement system as part of a continuing effort to reduce healthcare costs. But as a result, many patients come home "quicker and sicker," and in need of some form of care or help that family or friends may not be able to offer. Community-based healthcare services are expanding, giving patients more options for assistance at home.

History

It is helpful to have some basic information about the evolution of home care in order to understand the public's demand for quality healthcare, cost containment, and the benefits of advances in both medical and communication technologies. Members of Roman Catholic religious orders in Europe first delivered home care in the late seventeenth century. Today, there are many home care agencies and visiting nurse associations (VNAs) that continue to deliver a wide range of home care services to meet the specific needs of patients throughout the United States and Canada.

Social factors have historically influenced home care delivery, and continue to do so today. Before the 1960s, home care was a community-based delivery system that provided care to patients whether they could pay for the services or not. Agencies relied on charitable contributions from private citizens or

WWW.BOOKBAZ.IR

charitable organizations, as well as some limited government funding. Life expectancy of the United States population began to rise as advances in medical science saved patients who might have died in years past. As a result, more and more elderly or disabled people required medical care in their homes and in institutions. In response, the federal government put Medicare and Medicaid programs into place in 1965 to help fund and regulate healthcare delivery for this population.

Funding and regulation

Government involvement resulted in regulations that changed the focus of home care from a nursing care delivery service to care delivery under the direction of a physician. Home care delivery is paid for either by the government through Medicare and/or Medicaid; by private insurance or health maintenance organizations (HMOs); by patients themselves; or by certain nonprofit community, charitable disease advocacy organizations (e.g., American Cancer Society), or faith-based organizations.

Home care delivery services provided by Medicare-certified agencies are tightly regulated. For example, a patient must be homebound in order to receive Medicare-reimbursed home care services. The homebound requirement—one of many—means that the patient must be physically unable to leave home (other than for infrequent trips to the doctor or hospital), thereby restricting the number of persons eligible for home care services. Private insurance companies and HMOs also have certain criteria for the number of visits that will be covered for specific conditions and services. Restrictions on the payment source, the physician's orders, and the patient's specific needs determine the length and scope of services.

Assessment and implementation

Since home care nursing services are provided on a part-time basis, patients, family members, or other caregivers are encouraged and taught to do as much of the care as possible. This approach goes beyond payment boundaries; it extends to the amount of responsibility the patient and his or her family or caregivers are willing or able to assume in order to reach expected outcomes. Nurses who have received special training as case managers visit the patient's home and draw up a plan of care based on assessing the patient, listing the diagnoses, planning the care delivery, implementing specific interventions, and evaluating outcomes or the efficacy of the implementation phase. Planning the care delivery includes assessing the care resources within the circle of the patient's caregivers.

At the time of the initial assessment, the visiting nurse, who is working under a physician's orders, enlists professionals in other disciplines who might be involved in achieving expected outcomes, whether those outcomes include helping the patient return to a certain level of health and independence or maintaining the existing level of health and mobility. The nurse provides instruction to the patient and caregiver(s) regarding the patient's particular disease(s) or condition(s) in order to help the patient achieve an agreed-upon level of independence. Home care nurses are committed to helping patients make good decisions about their care by providing them with reliable information about their conditions. Since home care relies heavily on a holistic approach, care delivery includes teaching coping mechanisms and promoting a positive attitude to motivate patients to help themselves to the extent that they are able. Unless the patient is paying for home care services out of pocket and has unlimited resources or a specific private long-term care insurance policy, home care services are scheduled to end at some point. Therefore, the goal of most home care delivery is to move both the patient and the caregivers toward becoming as independent as possible during that time.

Professional implications

Home care delivery is influenced by a number of variables. Political, social, and economic factors place significant constraints on care delivery. Differences among nurses, including their level of education, years of work experience, type of work experience, and level of cultural competence (cross-cultural sensitivity) all influence care delivery to some extent.

Some of the professional issues confronting home care nurses include:

- legal issues
- ethical concerns
- safety issues
- nursing skills and professional education

Legal issues

The legal considerations connected with delivering care in a patient's private residence are similar to those of care delivered in healthcare facilities, but have additional aspects. For example, what would a home care nurse do if she or he had heard the patient repeatedly express the desire not to be resuscitated in case of a **heart attack** or other catastrophic event, and during a home visit, the nurse finds the patient unresponsive and cannot find the orders not to resuscitate in the patient's chart? What happens if the patient

falls during home care delivery? While processes, protocols, and standards of practice cannot be written to address every situation that may arise in a domestic setting, timely communication and strong policy are essential to keep both patients and home care staff free of legal liability.

Ethical concerns

Ethical implications are closely tied to legal implications in home care—as in the case of missing do-not-resuscitate (DNR) orders. For example, what measures are appropriate if a home care nurse finds a severe diabetic and recovered alcoholic washing down a candy bar with a glass of bourbon? The patient is in his or her own residence and has the legal right to do as he or she chooses. Or what about the family member who has a bad fall while the nurse is in the home providing care? Should the nurse care for that family member as well? What is the nurse's responsibility to the patient when he or she notices that a family member is taking money from an unsuspecting patient? Complex ethical issues are not always addressed in policy statements. Ongoing communication between the home care agency and the nurse in the field is essential to address problematic situations.

Safety issues

Safety issues in home care require attention and vigilance. The home care nurse does not have security officers readily available if a family member becomes violent either toward the healthcare worker or the patient. Sometimes, home care staff is required to visit patients in high-crime areas or after dark. All agencies should have some type of supervisory personnel available 24 hours a day, seven days a week, so that field staff can reach them with any concerns. Also, clear policy statements that cover issues of personal safety must be documented and communicated regularly and effectively.

Technological advances

With advances in technology and the increased effort to control cost, home care delivery services are using telecare, which uses communications technology to transmit medical information between the patient and the healthcare provider. Providing care to patients without being in their immediate presence is a relatively new form of home nursing, and is not without its problems. While some uncertainty exists regarding legal responsibilities and the potential for liability, much has been done to make telecare an effective way to hold costs down for some patients. Home care nurses who are required to make telecare visits should know what regulations exist in the particular state before providing care. The chief problem lies in diagnosing and prescribing over the phone. Technological advances have enabled patients to access telecare through the Internet using personal computers or using televisions. With the most recent advances in telecare, the following services may now be offered:

- instant access to patient records
- prescriptions for treatment
- assessment of possible dangers to the patient
- evaluation of the patient's treatment and medication
- follow-up care

Homeopathic medicine

Definition

Homeopathy, or homeopathic medicine, is a holistic system of treatment that originated in the late eighteenth century. The name homeopathy is derived from two Greek words that mean "like disease." The system is based on the idea that substances that produce symptoms of sickness in healthy people will have a curative effect when given in very diluted quantities to sick people who exhibit those same symptoms. Homeopathic remedies are believed to stimulate the body's own healing processes. Homeopaths use the term "allopathy," or "different than disease," to describe the use of drugs used in conventional medicine to oppose or counteract the symptom being treated.

Purpose

Homeopathic physicians seek to cure their patients on the physical, mental and emotional levels, and each treatment is tailored to a patient's individual needs. Homeopathy is generally a safe treatment, as it uses medicines in extremely diluted quantities, and there are usually minimal side effects. Its non-toxicity makes it a good choice for the treatment of children. Another benefit of homeopathy is the cost of treatments; homeopathic remedies are inexpensive, often a fraction of the cost of conventional drugs.

Examples of popular homeopathic remedies

Aconite	Commonly known as monkshood, aconite is highly toxic. A nontoxic, diluted extract is used in homeopathy to treat symptoms similar to that of poison.
Allium cepa	Commonly known as red onion, homeopathic physicians use a diluted extract of red onion to treat symptoms similar to that of red onion—watery eyes, burning, etc.
Apis	Commonly known as the honey bee, apis as a homeopathic remedy is made from the body of the bee. It is used to treat symptoms similar to that of a bee sting—redness, swelling, etc.
Arnica	Commonly known as the mountain daisy, arnica is used by homeopaths to treat bruises, sprains, and strains.
Arsenicum album	Also known as ars alb, arsenicum album is a diluted form of arsenic, a metallic poison. It is used by homeopathic physicians to treat symptoms similar to the effects of arsenic poisoning—dehydration, burning pain, etc.
Belladonna	Commonly known as deadly nightshade, belladonna is used in homeopathy to treat symptoms of dry mouth, nausea, delirium, etc.
Bryonia	Commonly known as wild hops, bryonia is used in homeopathy to treat vomiting, diarrhea, inflammation, etc.
Calcarea carbonica	Also known as calcium carbonate or calc carb, calcarea carbonica is used in homeopathy to treat symptoms of exhaustion, depression, and anxiety.
Cantharis	Commonly known as Spanish fly, cantharis is used in homeopathy to treat conditions with symptoms of abdominal cramps, vomiting, diarrhea, convulsions, etc.
Chamomilla	Derived from German chamomile, chamomilla is used in homeopathy to treat irritability, impatience, etc. It is most often prescribed to children.
Ferrum phosphoricum	Also known as ferrum phos or iron phosphate, it is used to treat symptoms of low energy and anemia.
Gelsemium	Also known as yellow jasmine, gelsemium is used to treat conditions that affect vision, balance, thought, and locomotion.
Hepar sulphuris	Derived from the inner layer of oyster shells, hepar sulphuris is used to treat infection.
Hypericum perforatum	Commonly known as St. John's wort, hypericum is used to treated nerve damage.
Ignatia	Derived from the bean of a small tree, this homeopathic remedy is prescribed to treat conditions with symptoms such as headache, cramping, and tremors.
Ipecac	Ipecac induces vomiting and causes gastrointestinal distress. Homeopaths prescribe it to treat similar symptoms.
Kali bichromicum	Commonly known as potassium bichromate, kali bichromicum is a poison used also in textile dyes, wood stain, etc. Homeopaths use it to treat localized pain.
Lachesis	Derived from the venom of the bushmaster snake, this homeopathic remedy is used to treat conditions that cause the same symptoms as the venom.
Ledum	Also known as marsh tea, ledum is used to treat infections, most often from animal bites, stings, cuts, etc.
Lycopodium	Commonly known as club moss, lycopodium is used to treat diarrhea, stomach upset, etc.

continued

Examples of popular homeopathic remedies [CONTINUED]

Mercurius vivus	Also known as quicksilver, it is used to treat symptoms of sweats, shaking, nausea, etc.
Natrum muriaticum	Commonly known as salt, it is used to treat conditions that cause excessive thirst and salt cravings.
Phosphorus	Phosphorus is used to treat symptoms of excessive thirst, fatigue, and nervousness.
Pulsatilla	Pulsatilla is used to treat conditions that are accompanied by discharge, such as bedwetting, sinusitis, etc.
Rhus toxicodendron	Commonly known as poison ivy, homeopaths use it to treat conditions with symptoms of fever, swollen glands, and restlessness.
Ruta	Ruta, or rue, is used to treat conditions associated with pain and strain, such as tennis elbow, sciatica, etc.
Sepia	Sepia is the discharge used by the cuttlefish to disappear from a predator. Homeopaths use sepia to treat symptoms of apathy and weakness.
Silica	Also called flint, silica is used by homeopaths to treat conditions that cause weakness, sweating, and sensitivity to cold.
Sulphur	Sulphur is used to treat conditions with symptoms of itching, burning pains, and odor.

(Table by PreMediaGlobal. © Cengage Learning®.)

Homeopathic treatment has been shown effective in treating many conditions. Colds and flu may be effectively treated with aconite and bryonia. **Influenza** patients in a double-blind study found that they were twice as likely to recover in 48 hours when they took homeopathic remedies. Studies have been published in British medical journals confirming the efficacy of homeopathic treatment for **rheumatoid arthritis**. Homeopathic remedies are effective in treating infections, circulatory problems, respiratory problems, **heart disease**, depression and nervous disorders, migraine headaches, **allergies**, arthritis, and diabetes. Homeopathy is a good treatment to explore for acute and chronic illnesses, particularly if these are found in the early stages and where there is not severe damage. Homeopathy can be used to assist the healing process after surgery or **chemotherapy**.

Description

Origins

Homeopathy was founded by German physician Samuel Hahnemann (1755–1843), who was much disturbed by the medical system of his time, believing that its cures were crude and some of its strong drugs and treatments did more harm than good to patients. Hahnemann performed experiments on himself using Peruvian bark, which contains quinine, a **malaria** remedy. He concluded that in a healthy person, quinine creates the same symptoms as malaria, including fevers and chills, which is the reason why it is effective as a remedy. He then began to analyze the remedies available in nature by what he called provings. Provings of homeopathic remedies are still compiled by dosing healthy adults with various substances and documenting the results, in terms of the dose needed to produce the symptoms and the length of the dose's effectiveness. The provings are collected in large homeopathic references called *materia medica* or materials of medicine.

Hahnemann formulated these principles of homeopathy:

- Law of Similars (like cures like)
- Law of the Infinitesimal Dose (The more diluted a remedy is, the more potent it is.)
- illness is specific to the individual

Hahnemann's Law of Similars was based on thinking that dated back to Hippocrates in the fourth century B.C. It is the same thinking that provided the basis for vaccines created by Edward Jenner (1749–1823) and Louis Pasteur (1822–1895). These vaccines provoke a reaction in the individual that protects against the actual disease. Allergy treatments work the same way. By exposing a person to minute quantities of the allergen, the person's tolerance levels are elevated.

The Law of the Infinitesimal Dose has always caused controversy among those outside the field of homeopathy. Hahnemann contended that as he diluted his remedies with water and alcohol and succussed, or shook, them, the remedies actually worked more effectively. In fact, diluted homeopathic remedies may have no chemical trace of the original substance. Practitioners believe that the electromagnetic energy of the original substance is retained in the dilution, but toxic side effects of the remedy are not. It is this electrochemical "message" that stimulates the body to heal itself, although there is no scientific proof of this.

Homeopathic practitioners believe that illness is specific to an individual. In other words, two people with severe headaches may not receive the same remedies. The practitioner will ask the patient questions about lifestyle, dietary habits, and personality traits, as well as specific questions about the nature of the **headache** and when it occurs. This information gathering is called profiling or case-taking.

Acute homeopathic prescribing is that part of homeopathy that treats illness that has an abrupt

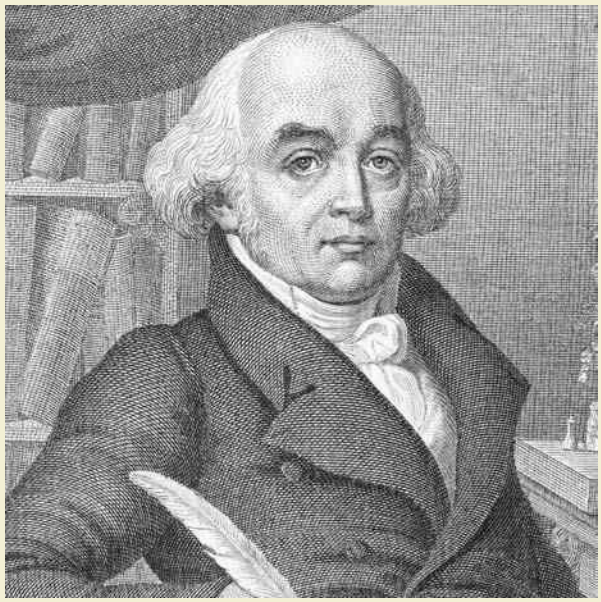
SAMUEL HAHNEMANN (1755–1843)



(© Bettmann/Corbis.)

Samuel Christian Hahnemann created and developed the system called homeopathy. It is also known as *similia similibus curentor* or like cures like. Although his new methods initially met with ridicule and criticism, by the time of his death they were accepted the world over as a result of the great success he had with his new cure.

Hahnemann was born in Meissen, Saxony (now part of Germany) into a financially challenged middle class family. His parents initially educated him at home, where his father taught him never to accept anything he learned without first questioning it. He graduated as a physician at Erlangen in 1779 after studying at universities in Leipzig and Vienna. He was also fluent in English, German, Italian, French, Greek, Arabic, Latin and Hebrew.

At age 27 he married his first wife, Johanna Henriette Kuchler, the daughter of an apothecary, with whom he had 11 children.

Living in poverty, Hahnemann began practicing medicine in 1781 and translating scientific texts to supplement his income. He studied chemistry and pharmacy. However, he grew increasingly disillusioned with medicine as he saw his children repeatedly battle illness, and he and eventually gave it up entirely.

He discovered the concept of homeopathy when considering the effect of quinine on malaria, and went on to cure soldiers and then sufferers of a typhus epidemic with astounding success. Several of his children aided him in his research. He documented his discoveries in the *Organon*, a treatise on his work. Homeopathy also proved its worth in 1831 when there was an outbreak of cholera. Hahnemann used homeopathic treatment with a 96% success rate, compared to the 41% of allopathic medicine. He also wrote his *Materia Medica Pura*, which details his research and his remedies.

Hahnemann's wife Johanna died in 1830. In 1834, Hahnemann met his second wife, Marie Melanie d'Hervilly. They were happily married until his death in Paris on July 2, 1843, at the age of 88. Hahnemann continued to practice homeopathy and lectured on the subject until his death.

onset and needs immediate attention. In homeopathic medicine, acute refers primarily to the speed of onset and self-limiting character of the disorder rather than its seriousness. Colds, influenza, sore throats, insect stings, cuts, **bruises**, **vomiting**, **diarrhea**, **fever**, muscle aches, and short-term **insomnia** are all examples of conditions that are treated by acute prescribing. The remedies given in acute homeopathic prescribing are intended to stimulate the body's internal ability to heal itself; they do not kill germs or suppress symptoms. Acute prescribing can be done—within limits—by patients at home, as well as by homeopathic practitioners. Study courses, self-treatment guides, and homeopathic home medicine kits are now available by mail order from homeopathic pharmacies and educational services.

Constitutional homeopathic prescribing, also called classical prescribing, is a holistic system of medicine that has been practiced for more than 200 years. Unlike acute homeopathic prescribing, constitutional prescribing refers to the selection and administration of homeopathic preparations over a period of time for treatment related to what practitioners call miasmic disorders, those caused by an inherited predisposition to a disease. The term miasm comes from a Greek word meaning stain or pollution. As in acute prescribing, constitutional prescribing is holistic in that it is intended to treat the patient on the emotional and spiritual levels of his or her being as well as the physical. Constitutional prescribing is also aimed at eventual cure of the patient, not just suppression or relief of immediate symptoms.

A visit to a homeopath can be a different experience than a visit to a regular physician. The initial visit often includes a long questionnaire about a patient's medical and family history, and then a long interview

with the practitioner, who prompts the patient with many questions. Sometimes a homeopathic practitioner will use lab tests to establish a patient's general level of health. The initial interview usually lasts 1–2 hours.

Homeopathic case-taking for constitutional prescribing is similar to that for acute prescribing, but more in-depth. The initial interview generally takes 1–2 hours. The practitioner is concerned with recording the totality of the patient's symptoms and the modalities that influence their severity. Also included are general characteristics about the patient and his or her lifestyle choices. For example, a practitioner might ask the patient if he or she likes being outside or is generally hot or cold. There is also an emphasis on the patient's lifetime medical history, particularly records of allopathic treatments.

Homeopathic classification of symptoms

Homeopathic practitioners use the word symptom in a more inclusive fashion than traditional medicine. In homeopathy, symptoms include any change that the patient experiences during the illness, including changes in emotional or mental patterns.

Homeopaths classify symptoms according to a hierarchy of four categories for purposes of acute prescribing:

- Peculiar symptoms. These are symptoms unique to the individual that do not occur in most persons with the acute disease. Homeopaths make note of peculiar symptoms because they often help to determine the remedy.
- Mental and emotional symptoms. These are important general symptoms that inform the homeopath about the patient's total experience of the disorder.
- Other general symptoms. These are physical symptoms felt throughout the patient's body, such as tiredness, changes in appetite, or restlessness.
- Particular symptoms. Particular symptoms are localized in the body; they include such symptoms as nausea, skin rashes, headache, etc.

Miasms

Homeopaths regard the patient's symptom profile as a systemic manifestation of an underlying chronic disorder called a miasm. Miasms are serious disturbances of what homeopaths call the patient's vital force that are inherited from parents at the time of conception. Hahnemann believed that the parents' basic lifestyle, their emotional condition, and habitual diet, and even the atmospheric conditions at the time of conception would affect the number and severity of miasms passed on to the child. Hahnemann himself distinguished three miasms: the psoric, which he considered the most universal source of chronic disease in humans; the syphilitic; and the sycotic, which he attributed to **gonorrhea**. Later homeopaths identified two additional miasms, the cancernic and the tuberculinic. The remaining major source of miasms is allopathic medicine. It is thought that specific allopathic treatments—particularly **smallpox** vaccinations, cortisone preparations, major tranquilizers, and antibiotics—can produce additional layers of miasms in the patient's constitution. There are no credible, mainstream scientific studies that support this. Constitutional prescribing evaluates the person's current state or miasmic picture, and selects a remedy intended to correct or balance that state. The homeopath may prescribe a different remedy for each miasmic layer over time, but gives only one remedy at a time directed at the person's current state. The basic principle governing the prescription of each successive remedy is the law of similars, or "like cures like."

Theory behind homeopathy

The purpose of homeopathy is the restoration of the body to homeostasis, or healthy balance, which is its natural state. The symptoms of a disease are regarded as the body's own defensive attempt to correct its imbalance, rather than as enemies to be defeated. Because a homeopath regards symptoms as positive evidence of the body's inner intelligence, he or she will prescribe a remedy designed to stimulate this internal curative process, rather than suppress the symptoms.

In homeopathy, the curative process extends beyond the relief of immediate symptoms of illness. Healing may come in stages, as the practitioner treats layers of symptoms that are remnants of traumas or chronic disease in the patient's past. This is part of Hering's Laws of Cure, named for Constantine Hering, the father of homeopathy in the United States. Hering believed that healing starts from the deepest parts of the body to the extremities, and from the upper parts of the body to the lower parts. Hering's Laws also state that homeopaths should treat disease symptoms in reverse chronological order, from the most recent to the oldest, restoring health in stages. Sometimes, the patient may feel worse before feeling better. This is called a healing crisis.

Hering enunciated three laws or principles of the patterns of healing that are used by homeopaths to evaluate the effectiveness of specific remedies and the overall progress of constitutional prescribing:

WWW.BOOKBAZ.IR

- Healing progresses from the deepest parts of the organism to the external parts. Homeopaths consider the person's mental and emotional dimensions, together with the brain, heart, and other vital organs, as a person's deepest parts. The skin, hands, and feet are considered the external parts.
- Symptoms appear or disappear in the reverse of their chronological order of appearance. In terms of constitutional treatment, this law means that miasms acquired later in life will resolve before earlier ones.
- Healing proceeds from the upper to the lower parts of the body.

When prescribing a remedy, homeopaths will match a patient's symptoms with the proper remedy in a repertory or *materia medica* that has been compiled throughout the history of homeopathy. Classical homeopaths prescribe only one remedy at a time. However, it is becoming more common, especially in Europe, to use combination formulas of several remedies for the treatment of some combinations of symptoms.

Acute homeopathic prescribing is thought to benefit a wide range of ailments. These include **altitude sickness**, Bell's palsy, the **common cold**, allergies, coughing, **dengue fever**, **dysentery**, earaches, migraine headaches, fever, **food poisoning**, grief, influenza, **motion sickness**, **shock**, **sore throat**, surgical complications, and reactions to vaccinations and drug therapy. Acute remedies may also be prescribed to treat insect stings, animal bites, and problems related to **poison oak** and **poison ivy**. It may be further employed in treating injuries including black eyes, **burns**, bruises, concussions, cuts, damaged tendons and ligaments, **dislocations**, **fractures**, herniated discs, nosebleeds, puncture **wounds**, sprains, and strains.

In constitutional prescribing, one dose of the selected remedy is given. Patients then wait 2–6 weeks before following up with the homeopath, while the body begins the healing process. At the follow-up visit, the remedy may be repeated, or a different remedy prescribed. The preparation, selection, administration, and storage of remedies for constitutional prescribing are the same as for acute prescribing.

Constitutional homeopathic prescribing is not appropriate for diseases or health crises requiring emergency treatment, whether medical, surgical, or psychiatric. In addition, constitutional prescribing should not be self-administered. Although home treatment kits of homeopathic remedies are available for acute self-limited disorders, the knowledge of homeopathic theory and practice required for constitutional evaluation is beyond the scope of most patients. Patients who are also seeing an allopathic doctor should make sure the physician is aware of the homeopathic treatment.

Homeopathic remedies

Homeopathic remedies are almost always made from natural materials—plant, animal, or mineral substances—that have been treated to form base tinctures or nonsoluble powders. Liquid extracts are then potentized, or increased in power, by a series of dilutions and succussions, or shakings. It is thought that succussion is necessary to transfer the energy of the natural substance to the solution. In addition, the potency of the remedy is regarded as increasing with each dilution. After the tincture has been diluted to the prescribed potency, the resulting solution is added to a bottle of sucrose/lactose tablets, which are stored in a cool, dark place. If the remedy is not soluble in water, it is ground to a fine powder and triturated with powdered lactose to achieve the desired potency.

There are several hundred homeopathic remedies. Homeopathic medicines are usually formulated from diluted or triturated natural substances, including plants, **minerals**, or even venom from snakes or stinging insects. Some remedies may be given in a spray, ointment, or cream, but the most common forms of administration are liquid dilutions and two sizes of pellets, or cylindrical tablets (for triturated remedies). A dose consists of one drop of liquid; 10–20 small pellets; or 1–3 large pellets. Since the remedies are so dilute, the exact size of the dose is not of primary importance. The frequency of dosing is considered critical, however; patients are advised not to take further doses until the first has completed its effect.

Homeopathic remedies can be kept indefinitely with proper handling. Proper handling includes storing the remedies in the original bottles and discarding them if they become contaminated by sunlight or other intense light; temperatures over 100°F (37.8°C); vapors from camphor, mothballs, or perfume; or from other homeopathic remedies being opened in the same room at the same time.

The choice of a specific remedy is guided by the patient's total symptom profile rather than by the illness. Homeopathic remedies are prescribed according to the law of similars, which holds that a substance that produces specific symptoms in healthy people cures those symptoms in sick people when given in highly diluted forms. For example, a patient with influenza who is irritable, headachy, and experiencing joint or muscle pains is likely to be given *bryonia* (wild hops), because this plant extract would cause this symptom cluster in a healthy individual.

Patients are instructed to avoid touching homeopathic medicines with their fingers. The dose can be poured onto a piece of white paper or the bottle's cap and tipped directly into the mouth. Homeopathic remedies are not taken with water; patients should not eat or drink anything for 15–20 minutes before or after taking the dose.

Homeopathic remedies may lose their potency if used at the same time as other products. Some homeopathic practitioners recommend the avoidance of mint and mentholated products (toothpastes, candies, chewing gum, mouth rinses), as well as camphor and camphorated products (including eucalyptus and Tiger Balm), patchouli and other essential oils, moth balls, strong perfumes, aftershaves, scented soaps, **stress**, x rays, coffee, nicotine, recreational drugs (**marijuana**), and certain therapeutic drugs (most notably cortisone and prednisone) during treatment. Patients are also advised to avoid electric blankets and dental work, as these are thought to adversely affect homeopathic therapy. Homeopathic remedies should never be placed near magnets.

Practitioners caution that high-potency preparations should be used only under the supervision of a homeopathic practitioner.

Healing crises

Homeopaths use Hering's laws to explain the appearance of so-called healing crises, or aggravations, in the course of homeopathic treatment. It is not unusual for patients to experience temporary worsening of certain symptoms after taking their first doses of homeopathic treatment. For example, a person might notice that arthritic pains in the shoulders are better but that the hands feel worse. Homeopaths see aggravation as a positive sign that the remedy is a good match for the patient's symptoms. The healing crisis, which happens when the patient is undergoing treatment for layers of symptoms, may also cause the patient to feel worse before feeling better. Some patients can experience emotional disturbances like weeping or depression, if suppressed emotional problems led to the illness in the first place. In constitutional prescribing, a remedy that removes one of the patient's miasmic layers will then allow the symptoms of an older miasm to emerge. Thus, the patient may find that a physical disease is followed by a different set of physical problems or by emotional symptoms.

Precautions

Although homeopathic remedies sometimes use substances that are toxic, they are diluted and prescribed in non-toxic doses. Remedies should be prescribed by a homeopathic practitioner. Those preparing to take homeopathic remedies should also avoid taking antidotes, substances, which homeopathic doctors believe cancel the effects of their remedies. These substances include alcohol, coffee, peppermint (in toothpaste and mouthwash), camphor (in salves and lotions), and very spicy foods. Homeopathic medicine should also be handled with care, and should not be touched with the hands or fingers, which can contaminate it.

Research and general acceptance

Since the early 1900s, when the American Medical Association and pharmacists waged a battle against it, homeopaths believe that homeopathy has been neglected and sometimes ridiculed by mainstream medicine. Much of this is because there are few controlled scientific studies of homeopathy that would meet the criteria for approval by the U.S. Food and Drug Administration (FDA), or for acceptance for publication in the major reputable medical journals in the United States. Aside from politics, part of the reason for this skepticism is that there are some aspects of homeopathy that have not been completely explained scientifically. For instance, homeopaths have found that the more they dilute and succuss a remedy, the greater effect it seems to have on the body. Some homeopathic remedies are so diluted that not even a single molecule of the active agent remains in a solution. Also, homeopathy puts an emphasis on analyzing symptoms and then applying remedies to these symptoms, rather than working by classifying diseases. Thus, some people with the same disease may require different homeopathic medicines and treatments. Furthermore, conventional medicine strives to find out how medicines work in the body before they use them; homeopathy is less concerned with the intricate **biochemistry** involved than with whether a remedy ultimately works and heals holistically. For all these reasons, conventional medicine claims that homeopathy is not scientific.

The cost of homeopathic care can vary. The cost of visits will be comparable to conventional medicine, with initial visits ranging $50–300. Non-M.D. homeopaths can charge $50–250. Follow-up visits are less, at about $35–100. Homeopathic medicine is significantly cheaper than pharmaceuticals, and most remedies cost between $2 and $10. Homeopaths rarely use lab tests, which reduces the cost of treatment further. In general, homeopathy is much more economical than conventional medicine. In 1991, the French government did a study on the cost of homeopathic medicine, and found that it costs half as much to treat patients, considering

WWW.BOOKBAZ.IR

KEY TERMS

Acute prescribing—Homeopathic treatment for self-limiting illnesses with abrupt onset.

Allopathy—Conventional medical treatment of disease symptoms that uses substances or techniques to oppose or suppress the symptoms.

Law of similars—The basic principle of homeopathic medicine that governs the selection of a specific remedy. It holds that a substance of natural origin that produces certain symptoms in a healthy person will cure those same symptoms in a sick person.

Modalities—The factors and circumstances that cause a patient's symptoms to improve or worsen.

Mother tincture—The first stage in the preparation of a homeopathic remedy, made by soaking a plant, animal, or mineral product in a solution of alcohol.

Potentization—The process of increasing the power of homeopathic preparations by successive dilutions and succussions of a mother tincture.

Succussion—The act of shaking diluted homeopathic remedies as part of the process of potentization.

Trituration—The process of diluting a nonsoluble substance for homeopathic use by grinding it to a fine powder and mixing it with lactose powder.

all costs involved. The study did not look at the effectiveness of homeopathy treatment versus conventional treatment.

When homeopaths are licensed professionals, most insurance companies will pay for their fees. Consumers should consult their insurance policies to determine individual regulations. Insurance usually will not cover visits to homeopathic practitioners or homeopathic medicine.

There continue to be many studies that homeopaths believe affirm the effectiveness of homeopathic treatments. In 1991, the *British Medical Journal* published a large analysis of homeopathic treatments that were given over the course of 25 years. This project involved over 100 studies of patients with problems ranging from vascular diseases, respiratory problems, infections, stomach problems, allergies, recovery from surgeries, arthritis, **trauma**, psychological problems, diabetes, and others. The study found improvement with homeopathic treatment in most categories of problems, and concluded that the evidence was "sufficient for establishing homeopathy as a regular treatment for certain indications."

Homocysteine

Definition

Homocysteine is a naturally occurring amino acid found in blood plasma. High levels of homocysteine in the blood are believed to increase the chance of **heart disease**, **stroke**, Alzheimer's disease, and **osteoporosis**.

Description

Homocysteine is a sulfur-containing amino acid that occurs naturally in all humans. It is broken down

in the body through two metabolic pathways. The chemical changes that must occur to break down homocysteine require the presence of **folic acid** (also called folate) and **vitamins** B^6 and B^{12}. The level of homocysteine in the blood is influenced by the presence of these substances.

Homocystinuria is a rare genetic disorder that occurs in about one in every 200,000 individuals. This congenital metabolic disorder causes large amounts of homocysteine to be excreted in the urine. Homocystinuria is associated **intellectual disability** (ID) and the development of heart disease before age 30.

In the late 1960s, doctors documented that individuals with homocystinuria developed narrowing of the arteries at a very early age, sometimes even in childhood. Although homocystinuria is rare, this finding stimulated research on whether people who did not have homocystinuria but who did have unusually high levels of homocysteine in their blood were at greater risk of developing heart disease or stroke.

Many risk factors, including family history of heart disease, **smoking**, **obesity**, lack of **exercise**, diabetes, high levels of low-density lipoprotein **cholesterol** (LDL or "bad" cholesterol), low levels of high-density lipoprotein cholesterol (HDL or "good" cholesterol), and high blood pressure have been documented to increase the risk of stroke and heart disease. With so many other risk factors, it has been difficult to determine whether high levels of homocysteine are an independent risk factor for the development of these diseases. However, a substantial number of controlled, well-designed, and well-documented studies have shown that individuals who have high levels of homocysteine in the blood are at increased risk of developing blocked blood vessels, a condition known as occlusive arterial disease or at risk to worsen atherosclerosis (hardening of the arteries).

In the 2000s, studies also suggested that high levels of homocysteine were associated with poorer mental functioning, leading to ongoing investigations into the role of homocysteine in Alzheimer's disease. Additional studies have also suggested that high levels of homocysteine can lead to osteoporosis and an increased risk of broken bones in the elderly. Homocysteine was being tested in half a dozen clinical trials to determine its role in these and several other conditions. Information on clinical trials that are enrolling patients can be found online at www.clinicaltrials.gov.

Causes and symptoms

Homocysteine is thought to irritate the lining of the blood vessels, causing them to become scarred, hardened, and narrowed. This increases the work the heart must do, leading to heart disease. High levels of homocysteine also cause increased blood clotting. **Blood clots** can decrease or block the flow of blood through blood vessels, resulting in strokes and heart attacks. If and how homocysteine directly plays a role in osteoporosis and Alzheimer's disease is not clear.

The level of homocysteine in the blood naturally varies with age, gender, diet, hereditary factors, and general health, but it is estimated that 5–10% of the population has homocysteine levels that are considered high. With the exception of rare individuals who have congenital homocystinuria, people with high blood levels of homocysteine do not have any obvious signs or symptoms.

Diagnosis

The American Heart Association and the American College of Cardiology do not recommend routine screening of homocysteine levels, but they do recommend screening as part of a cardiac risk assessment for individuals who have a family history of **coronary artery disease** but no obvious symptoms of heart disease. The level of homocysteine in the blood can be measured with a simple blood test that is often, but not always, done after **fasting**. Homocysteine levels of 12 mmol/L are considered normal and levels below 10 mmol/L are considered desirable.

Treatment

Lowering homocysteine blood levels is linked to increasing the intake of folic acid and vitamins B_6 and B_{12}. The healthiest way to increase intake is by eating more foods that are high in these substances. Good sources of folic acid, vitamin B_6, and vitamin B_{12} include green leafy vegetables, fortified breakfast cereals, lentils, chickpeas, asparagus, spinach, and most beans. Taking a daily multivitamin is also a way to increase the levels of these substances. However, megadoses of folic acid, vitamin B_6, and vitamin B_{12} are not recommended. Individuals should discuss dosage with their doctor before beginning any supplements. It is important to note that a direct link between increased intake of folic acid, vitamin B_6, and vitamin B_{12} and decreased incidence stroke and **heart attack** has not been proven. However, one study published in the *Journal of the American Medical Association* found that women whose folic acid levels were in the lowest 25% were 69% more likely to die of coronary problems than women whose folic acid levels were in the top 25%.

WWW.BOOKBAZ.IR

Individuals with homocystinuria are treated with the drug betaine (Cystadane). This is a powder dissolved in water, juice, or milk and drunk usually twice a day with meals. This drug is not normally used simply to lower high levels of homocysteine in the absence of congenital disease.

Prognosis

Individuals who increase the folic acid, vitamin B_6, and vitamin B_{12} in their diet are expected to see a decrease in blood levels of homocysteine and as a result decrease their risk of heart disease and stroke.

Prevention

Certain drugs are suspected of increasing the level of homocysteine in the blood. People using these drugs should discuss with their doctor the advisability of increasing their intake of folic acid, vitamin B_6, and vitamin B_{12}. These drugs include:

- lipid-lowering drugs such as fenofibrate (Tricor) and bezafibrate (Bezalip)
- metformin (Glucophage), a drug to modify insulin resistance
- anti-epileptic drugs such as phenobarbital, phenytoin (Dilantin), primidone (Mysoline) and carbamazepine (Tegretol)
- levadopa (Sinemet) for treatment of Parkinson's disease
- methotrexate (Rheumatrex, Trexall) for treatment of cancer, psoriasis, rheumatoid arthritis, and systemic lupus erythematosus
- androgen treatment
- nitrous oxide (laughing gas), a mild anesthetic

Hookworm disease

Definition

Hookworm disease is an illness caused by one of two types of S-shaped worms that infect the intestine of humans (the worm's host).

Description

Two types of hookworm are responsible for hookworm disease in humans. *Necator americanus* and *Ancylostoma duodenale* have similar life cycles and similar methods of causing illness. The adult worm of both *N. americanus* and *A. duodenale* is about 10 mm long, pinkish-white in color and curved into an S-shape or double hook.

Both types of hookworm have similar life cycles. The females produce about 10,000–20,000 eggs per day. These eggs are passed out of the host's body in feces. The eggs enter the soil, where they incubate. After about 48 hours, the immature larval form hatches out of the eggs. These larvae take about six weeks to develop into the mature larval form that is capable of causing human infection. If exposed to human skin at this point (usually bare feet walking in the dirt or bare hands digging in the dirt), the larvae will bore through the skin and ride through the lymph circulation to the right side of the heart. The larvae are then pumped into the lungs. There they bore into the tiny air sacs (alveoli)

A micrograph image of the head of the hookworm *Ancylostoma spp.* *(Photo Researchers, Inc.)*

of the lungs. Their presence within the lungs usually causes enough irritation to produce coughing. The larvae are coughed up into the throat and mouth, and are then swallowed and passed into the small intestine. It is within the intestine that they develop into the adult worm, producing illness in their human host.

A. duodenale is found primarily in the Mediterranean, the Middle East, and throughout Asia. *N. americanus* is common in tropical areas including Asia, parts of the Americas, and throughout Africa. Research suggests that at least 25% of all people in the world have hookworm disease. In the United States, 700,000 people are believed to be infected with hookworms at any given time.

Causes and symptoms

Hookworms cause trouble for their human host when the worms attach their mouths to the lining of the small intestine and suck the person's blood.

An itchy, slightly raised rash called "ground itch" may appear around the area where the larvae first bored through the skin. The skin in this area may become red and swollen. This lasts for several days and commonly occurs between the toes.

When the larvae are in the lungs, the patient may have a **fever**, **cough**, and some **wheezing**. Some people, however, have none of these symptoms.

Once established within the intestine, the adult worms can cause abdominal **pain**, decreased appetite, **diarrhea**, and weight loss. Most importantly, the worms suck between 0.03–0.2 mL of blood per day. When a worm moves from one area of the intestine to another, it detaches its mouth from the intestinal lining, leaving an irritated area that may continue to bleed for some time. This results in even further blood loss. A single adult worm can live for up to 14 years in a patient's intestine. Over time, the patient's blood loss may be very significant. Anemia is the most serious complication of hookworm disease, progressing over months or years. Children are particularly harmed by such anemia, and can develop heart problems, intellectual disabilities (ID), slowed growth, and delayed sexual development. In infants, hookworm disease can be deadly.

Diagnosis

Diagnosis of hookworm disease involves collecting a stool sample for examination under a microscope. Hookworm eggs have a characteristic appearance. Counting the eggs in a specific amount of feces allows the healthcare provider to estimate the severity of the infection.

Treatment

Minor infections are often left untreated, especially in areas where hookworm is very common. If treatment is required, the doctor will prescribe a three-day dose of medication. One to two weeks later, another stool sample will be taken to see if the infection is still present.

Anemia is treated with iron supplements. In severe cases, blood **transfusion** may be necessary. Two medications, pyrantel pamoate and mebendazole, are frequently used with good results.

Prognosis

The prognosis for patients with hookworm disease is generally good. However, reinfection rates are extremely high in countries with poor sanitation.

Prevention

Prevention of hookworm disease involves improving sanitation and avoiding contact with soil in areas with high rates of hookworm infection. Children should be required to wear shoes when playing outside in such areas, and people who are gardening should wear gloves.

Hormone replacement therapy

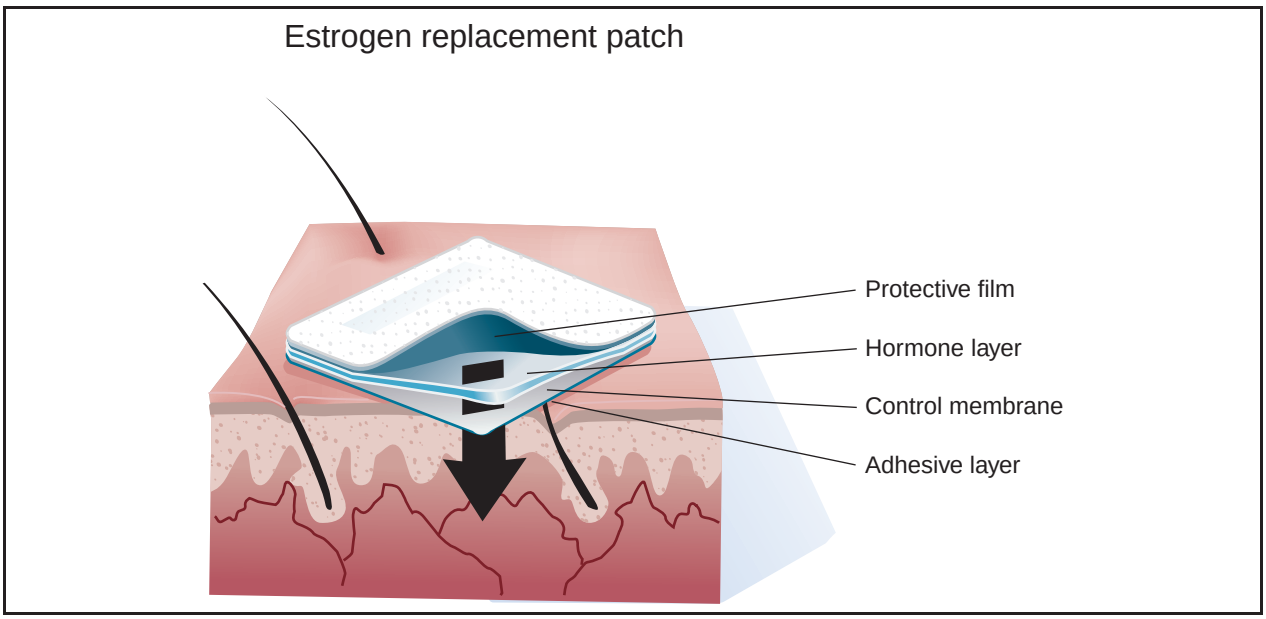
Definition

Hormone replacement therapy (HRT)—now more commonly called menopausal hormone therapy (MRT)—is the use of synthetic or natural female hormones to compensate for the decline in the body's hormone production that occurs when a woman enters **menopause**.

Purpose

HRT is used relieve physical symptoms associated with menopause—the stage of midlife development when a woman's menstrual periods become irregular

WWW.BOOKBAZ.IR



Estrogen replacement patches adhere to a patient's skin and slowly administer estrogen to the body. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

and eventually cease. Women usually begin the earliest stages of menopause—known as perimenopause—in their mid-30s. Over time the ovaries decrease their production of the sex hormones estrogen and progesterone. Women undergo natural menopause when they have their last menstrual period. Menopause is considered to be complete one year after the last menstruation. This most often occurs between the ages of 45 and 55. Women who have their ovaries removed undergo immediate surgical menopause.

In the years before and during menopause the levels of estrogen and progesterone fluctuate irregularly. Following menopause, estrogen levels are about one-tenth of premenopausal levels and progesterone is almost completely absent. Menopausal symptoms resulting from low estrogen that may be treated with HRT include:

- hot flashes
- vaginal dryness
- night sweats
- sleep disturbances
- mood swings
- frequent urination
- loss of sexual interest

HRT is also used to help prevent osteoporosis—a decrease in bone mass and density that causes the bones to become more fragile and can lead to **fractures**.

Demographics

At the turn of the twenty-first century, about 6 million American women were taking estrogen and progestin (a synthetic progesterone) as HRT. Although many women used HRT for only a couple of years to treat menopausal symptoms, some women used HRT indefinitely. Then, in 2002 and 2004, early results from the Women's Health Initiative (WHI) Hormone Program—a very large clinical study of HRT by the U.S. National Institutes of Health—indicated that postmenopausal women on HRT were at increased risk for **heart attack**, **stroke**, **blood clots**, and **breast cancer**. Since then, millions of women have stopped taking the hormones. Recent decreases in the incidence of breast cancer in the United States have been attributed, in part, to this reduction in HRT.

Description

Estrogen relieves menopausal symptoms and may help prevent **osteoporosis**. Women who have had their uterus removed can use estrogen alone for HRT. Otherwise women must take progesterone or progestin along with the estrogen to reduce the risk of thickening of the lining of the uterus and uterine cancer.

Estrogen for HRT is available in many forms including:

- oral pills
- transdermal skin patches

- implants
- injections
- vaginal ring inserts
- vaginal tablets
- vaginal creams
- gels
- emulsions
- sprays

Estrogen patches and pills can relieve hot flashes, night sweats, and vaginal dryness. Vaginal rings, tablets, and creams are used to treat vaginal dryness, although vaginal ring inserts may help relieve some urinary tract symptoms.

There are different types of estrogens. Estradiol is the most important type in premenopausal women. If synthetic estradiol is injected or applied to the skin—rather than taken by mouth—it appears to work in the same way as estradiol made in the body. Estrone is the form of estrogen that is produced by the body in postmenopausal women. Conjugated estrogen is a mixture of estrone and other estrogens. Estriol is a weaker form of estrogen produced by the breakdown of other estrogens in the body and is the type most commonly used in Europe for HRT. Estrogen taken as a pill is chemically changed in the liver. Some studies have suggested that estrogen that enters through the skin, bypassing the liver, may present less risk for serious blood clots, stroke, and possibly gallbladder disease. Non-oral forms of estrogen also may relieve symptoms at a lower dosage than oral estrogen.

Progesterone or progestin is available in various forms including:

- pills
- combined with estrogen in pills
- combined with estrogen in skin patches
- injections
- as an intrauterine device (IUD)
- gels
- vaginal suppositories

HRT doses and timing of the doses vary. Sometimes estrogen and progesterone are taken daily. Sometimes estrogen is taken daily, whereas progesterone or progestin is taken for 10–14 days every four weeks to mimic premenopausal hormone production. This approach can cause some spotting or bleeding. Various other dosing regimes are also used.

Common types of HRT include:

- generic estradiol pills
- Gynodiol (estradiol pill)
- Menest (esterified estrogen pill)
- generic estropipate pills
- generic estradiol skin patches
- Estraderm (estradiol skin patch)
- FemRing (estradiol vaginal ring)
- Estring (estradiol vaginal ring)
- Premarin vaginal cream (conjugated equine estrogen)
- generic medroxyprogesterone pills
- Prempro (estrogen-progestin combination pill)
- Prefest (estrogen-progestin combination pill)
- Climara Pro (estrogen-progestin skin patch)
- Combipatch (estrogen-progestin skin patch)

Some women prefer natural progesterone because they find that it lacks the side effects of synthetic progestin. Natural progesterone is also available as an over-the-counter **vitamin E** oil suspension that is absorbed through the skin.

"Natural" or bio-identical estrogens and progesterones are made from plants such as soy or yams. Some of these hormones are chemically identical to those made by the female body. Sometimes these hormones are formulated by a physician according to the requirements of individual women and are put together or compounded by a compounding pharmacist.

Women's ovaries secrete small amounts of the male sex hormone testosterone throughout their lives. Women who have had both ovaries surgically removed are sometimes given testosterone along with estrogen for HRT. Women also sometimes use 1% testosterone cream to relieve vaginal soreness.

Origins

Physicians began prescribing estrogen to menopausal women during the 1960s, when it was referred to as estrogen replacement therapy (ERT). The use of HRT grew rapidly, in part because—until the results of the WHI—it was widely believed that HRT reduced the risk of **heart disease**, stroke, and cancer in postmenopausal women.

Benefits

HRT can significantly improve quality of life for some women. The WHI and other studies have found that 70–90% of menopausal women who take estrogen have an average reduction of 75% in the frequency of hot flashes and night sweats. Estrogen supplementation also reduces vaginal dryness and urinary symptoms associated with menopause. Estrogen appears to improve **cholesterol** levels, lowering LDL ("bad" cholesterol) and raising HDL ("good" cholesterol),

WWW.BOOKBAZ.IR

although estrogen in pill form can cause increased triglycerides—fats in the blood. The estrogen patch does not seem to have this effect, but it also does not improve cholesterol levels to the same degree as the pill.

The WHI found that both estrogen-alone and estrogen-plus-progestin HRT lowered the risk of bone fractures. Estrogen-plus-progestin HRT also lowered the risk of colorectal cancer.

Precautions

Women aged 50–59 who have become menopausal within the past five years and are at low risk for heart disease can use HRT without increasing their risk for heart disease. However, they will have an increased risk of breast cancer, blood clots, and stroke:

- Women should take the lowest dose of HRT that relieves symptoms and for the shortest possible time.
- HRT should be re-evaluated every six months.
- Women should not use HRT if their symptoms are mild and can be managed with lifestyle and habit changes, such as quitting smoking, sleeping in a cooler room, reducing stress, exercising regularly, and limiting caffeine and alcohol.
- Women should not use HRT after the first 5–10 years post-menopause.
- HRT is ineffective for—and can even worsen—conditions such as mood swings, irritability, depression, anxiety, cognitive difficulties, reduced libido, urinary incontinence, back or joint pain, chronic pain, stiffness, or fatigue.
- Bio-identical hormones compounded in pharmacies are not regulated by the U.S. Food and Drug Administration (FDA) and have not been shown to be more effective or safer than other HRTs.

Common side effects of HRT include:

- fluid retention
- bloating
- weight gain
- breast tenderness or soreness
- spotting or a return of monthly periods
- cramping
- leg cramps
- vaginal discharge
- severe headaches
- hair loss
- nausea and vomiting
- acne
- moodiness
- depression
- shortness of breath
- dizziness

Potentially serious side effects of HRT include:

- tissue growth in the uterus (fibroids)
- abnormal growth (hyperplasia) of uterine tissue
- gallstones
- thrombophlebitis
- hypoglycemia
- thyroid disorders
- high blood pressure

HRT can interact with other medications, including:

- corticosteroids
- anticoagulants
- rifampin

Drugs that can cause liver damage when combined with estrogens include:

- acetaminophen (Tylenol), when used in high doses over long periods
- anabolic steroids such as nandrolone (Anabolin) or oxymetholone (Anadrol)
- medicine for infections
- antiseizure medicines such as divalproex (Depakote), valproic acid (Depakene), or phenytoin (Dilantin)
- antianxiety drugs, including chlorpromazine (Thorazine), prochlorperazine (Compazine), and thioridazine (Mellaril)

Estrogens can interfere with the effects of bromocriptine (Parlodel) used to treat Parkinson's disease and other conditions. Estrogens can increase the chance of toxic side effects from cyclosporine (Sandimmune).

Other conditions and allergies

HRT should not be used by women with:

- heart disease
- diabetes, high cholesterol, high blood pressure, family history of heart disease, or other risk factors for heart disease
- breast cancer
- cancer of the ovaries or uterus
- history of stroke
- abnormal undiagnosed vaginal bleeding
- liver disease
- gallstones or gallbladder disease

KEY TERMS

Estrodiol—The most physiologically active form of estrogen.

Estrogen—Any of several naturally occurring or synthetic steroid hormones that promote the growth and maintenance of the female reproductive system.

Menopause—The female developmental stage at which menstruation ceases.

Osteoporosis—A disease characterized by low bone mass and structural deterioration of bone tissue, leading to bone fragility.

Progesterone—A female steroid sex hormone that is secreted after ovulation to prepare the lining of the uterus for implantation with a fertilized egg and secreted by the placenta to maintain pregnancy.

Progestin—Any natural or synthetic hormone that causes the effects of progesterone.

Testosterone—The primary male sex hormone.

Women's Health Initiative (WHI)—A very large clinical study supported by the National Heart, Lung, and Blood Institute and the National Cancer Institute of the U.S. National Institutes of Health that is examining a wide range of women's health issues including HRT.

Preparation

Women who are considering HRT should carefully discuss the benefits and risks with their doctor. They should have a variety of tests including:

- a Pap smear
- breast examination and mammogram
- urinalysis
- bone density
- red blood cell count
- blood sugar levels
- cholesterol levels
- liver and thyroid function

Before prescribing HRT many doctors administer a progesterone challenge test to determine whether a woman is still producing estrogen. Bleeding after taking progesterone for 10 days indicates that a woman's ovaries are still making estrogen.

Aftercare

Women on HRT should have their blood pressure tested and breasts examined at least twice a year. They should have a complete physical on a yearly basis. Any abnormal bleeding may require a tissue biopsy or **dilatation and curettage** to rule out uterine cancer.

The HRT dosage should be tapered off over a period of several months rather than discontinued abruptly. The gradual reduction minimizes the possibility of hot flashes and other side effects.

Risks

The WHI Estrogen-plus-Progestin Study was halted prematurely in July 2002, when early results showed that the overall risks of Prempro outweighed the benefits, increasing the risk of breast cancer, heart disease, heart attack, stroke, serious blood clots in the legs and lungs, and **urinary incontinence**. Furthermore, the WHI Memory Study found that, in postmenopausal women aged 65 and older, estrogen-plus-progestin HRT doubled the risk for developing all types of **dementia**, including Alzheimer's disease.

The WHI Estrogen-Alone Study was halted prematurely in 2004, when researchers found an increased risk of stroke, blood clots, and urinary incontinence. It also found that estrogen alone did not reduce the risk of heart disease.

It is unclear whether the results of the WHI Hormone Therapy Study apply to all forms of HRT. The study used only oral HRT, rather than patches or other forms of delivery, and only specific forms of estrogen and progestin at specific doses. The increased risk for heart disease and dementia applied only to women over age 60.

Hospice

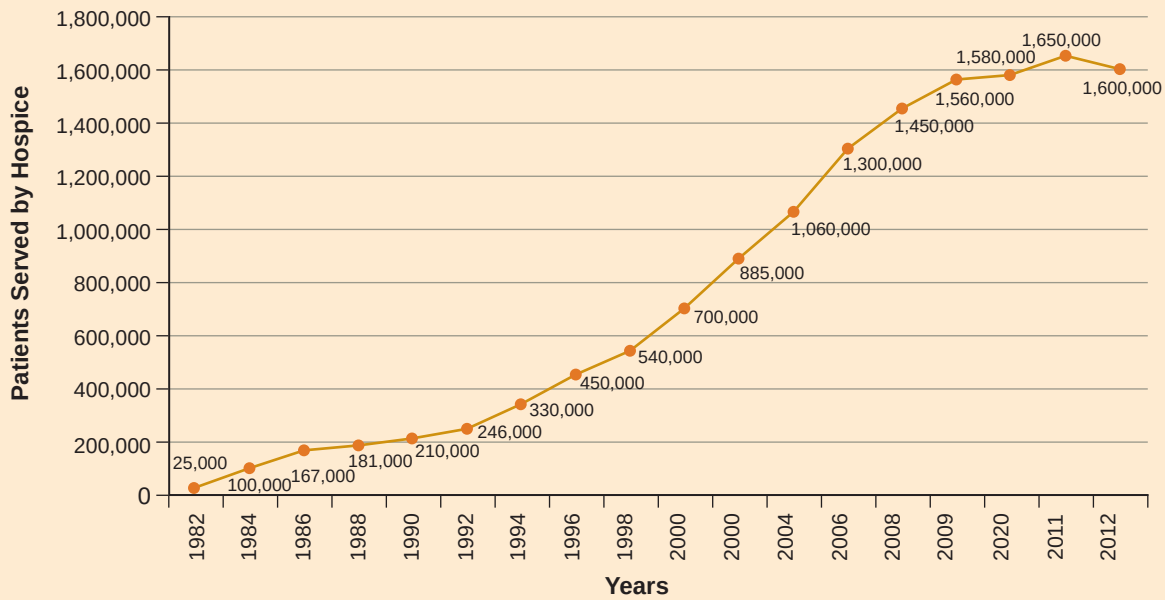
Definition

The term hospice refers to an approach to end-of-life care, as well as to a type of facility for supportive care of terminally ill patients. Hospice programs provide palliative, patient-centered care, and other services. Palliative care relieves discomfort, but does not improve the patient's condition or cure the disease. It includes medical care, pain management, and emotional and spiritual support designed with individual patients in mind. The goal of hospice care, whether delivered in the patient's home or in a health-care facility, is the provision of humane and compassionate medical, emotional, and spiritual care to patients who are dying.

Description

Most hospice care is delivered in patients' homes, although the hospice programs that direct the care may be based in medical facilities. Usually, a family member is the primary caregiver, and is supported by hospice staff members who make regular house visits to see the patient and the caregiver. Home health agency programs care for patients at home, while hospital-based programs may devote a special wing, unit, or floor to hospice patients. Freestanding independent for-profit hospices devoted exclusively to care of the terminally ill also exist. Most hospice programs offer a combination of services, both inpatient and home-care programs, allowing patients and families to use both as needed.

Approximately 5,500 hospice programs operated throughout the United States, and they offered care to some 1.65 million patients, according to the 2012 report of the National Hospice and Palliative Care Organization (NHPCO). This compares to 1998, when hospice programs in the United States cared for about 540,000 people.



Source: National Hospice and Palliative Care Organization. Available online at: http://www.nhpco.org/hospice-statistics-research-press-room/facts-hospice-and-palliative-care (accessed September 15, 2014).

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

One limitation of present hospice models is that most require physicians to estimate that the patient is not likely to live longer than six months. This requirement is related to criteria for Medicare eligibility. Unfortunately, it means that terminal patients with uncertain prognoses are often excluded from hospice care.

Origins

The hospice movement began in the United Kingdom during the middle of the 19th century. In Dublin, the Roman Catholic Sisters of Charity undertook to provide a clean, supportive environment for care for the terminally ill. Their approach spread throughout England and as far as Asia, Australia, and Africa, but until the early 1970s, it had not been accepted on any wide scale in the United States.

Two physicians, Drs. Cicely Saunders (1918–2005) and Elisabeth Kübler-Ross (1926–2004), are credited with introducing the hospice concept in the United States.

Dr. Saunders had originally trained as a nurse in England and afterward attended medical school. She founded St. Christopher's Hospice just outside of London in 1962. St. Christopher's pioneered an interdisciplinary team approach to the care of the dying. This approach made great strides in pain management and symptom control. Dr. Saunders also developed the basic tenets of hospice philosophy. These include:

- acceptance of death as the natural conclusion of life
- delivery of care by a highly trained, interdisciplinary team of health professionals who communicate among themselves regularly
- the emphasis of effective pain management and comprehensive home care services
- counseling for the patient, as well as bereavement counseling for the family after the patient's death
- ongoing research and education as essential features of hospice programs

During this same period, Dr. Kübler-Ross, a psychiatrist working in Illinois, published results from her ground-breaking studies of dying patients. Her books about the psychological stages of response to catastrophe and her lectures to health professionals helped to pave the way for the development and acceptance of hospice programs in the United States. She outlined five stages of "acceptance," which are not limited to use in counseling the dying. Many patients who become disabled—especially those whose disability and physical impairment are sudden occurrences—go through the same "grieving" process for the loss of their previous physical health or quality of life.

WWW.BOOKBAZ.IR

CICELY SAUNDERS(1918–2005)

Dame Cicely Saunders. *(Courtesy of St. Christopher's Hospice, London.)*

Cicely Saunders was born in London on June 22, 1918, the first of three children born into a wealthy family. She attended boarding school and was eventually accepted at St. Anne's College, Oxford. After the onset of World War II, she left St. Anne's to train as a Red Cross war nurse at the Nightingale Training School.

After the war, she trained at the Royal Cancer Hospital and in September 1947 she joined the staff of St. Thomas's Hospital's Northcote Trust, which specialized in cancer patients. At St. Thomas's, Saunders met David Tasma, a cancer patient from Poland with whom she fell in love. Saunders and Tasma's entire relationship was conducted in the confines of the hospital, with Saunders caring for him during his final days. Her experiences with Tasma and other patients convinced Saunders of the need for better-rounded care for the terminally ill. While Saunders resolved to continue her work with the dying, her concept of hospice care developed.

In 1959, Saunders began outlining her concepts for the modern hospice. In a paper titled "The Need," Saunders contrasted standard medical approaches to the terminally ill with her vision. A second paper, "The Scheme," outlines a plan for a 100-bed home for cancer patients and those with other terminal illnesses. She incorporated opportunities for spiritual reflection into her plan, including a chapel, staff theologians, and prayer time. Yet she remained adamant that religion not be forced on anyone. Once outlined, Saunders began raising funds for what became St. Christopher's in 1967. It is regarded as the model for the modern hospice movement. In 2001, Saunders and St. Christopher's were awarded the Conrad N. Hilton Humanitarian Prize.

Saunders died on July 14, 2005.

The first hospice programs in North America opened during the 1970s. In New Haven, Connecticut, the Yale University School of Medicine started a hospice home care program in 1974, adding inpatient facilities in 1979. In 1976, another hospice/home-care program, called the Hospice of Marin, began in northern California. After a slow start, interest in and enthusiasm for the hospice concept grew. Health professionals as well as the public at large embraced the idea of death with dignity. The notion of quality care at the end of life combined with grief counseling and bereavement care (counseling and support for families and friends of dying persons) gained widespread acceptance. The hospice movement also benefited from government efforts to contain health-care costs when reimbursement for inpatient hospital services was sharply reduced. Home-based hospice care is a cost-effective alternative to end-of-life care in a hospital or skilled nursing facility.

Purpose

A primary purpose of a hospice program is to provide palliative care. This can be a difficult concept for American health professionals who are trained to fight disease with the goal of cure, rather than accept death and dying as the natural, inevitable conclusion to life. Because of the nature of palliative care, health professionals who refer patients to, or who work in, hospice programs must become especially well informed about pain management and symptom control. In traditional medical settings, pain medication is often administered when the patient requests it, but hospice care approaches pain control quite differently. By administering pain medication regularly, before it is needed, hospice caregivers hope to prevent pain from recurring. Since addiction and other long-term consequences of narcotic analgesics are not a concern for the terminally ill, hospice caregivers focus on relieving pain as completely and effectively as possible. Hospice patients often have patient-controlled analgesia (PCA) pumps that allow them to control their pain medication.

Symptom relief often requires more than simply using narcotic analgesia. Hospices consider the patient and family (blood relatives as well as all persons who

KEY TERMS

Hospice—An approach for providing compassionate, palliative care to terminally ill patients and counseling or assistance for their families. The term may also refer to a hospital unit or freestanding facility devoted to the care of terminally ill patients.

Palliative—A type of care that is intended to relieve pain and suffering, but not to cure.

Patient-controlled analgesia (PCA)—An approach to pain management that allows the patient to control the timing of intravenous doses of analgesic drugs.

are close to the patient). Seeking to relieve physical, psychological, emotional, and spiritual discomfort, hospice teams rely on members of the clergy, pastoral counselors, social workers, psychiatrists, massage therapists, and trained volunteers to comfort patients and family members, in addition to the solace offered by nurses and physicians.

Beyond mainstream medicine, many hospices offer patients and families the opportunity to use complementary and alternative approaches to control symptoms and improve well being. Acupuncture, bodywork, massage therapy, aromatherapy, Reiki (energy healing), Native American ceremonies, herbal treatments, and other non-Western practices may be used to calm and soothe patients and their families.

The goal of freestanding hospices and even hospital-based programs is the creation and maintenance of warm, comfortable, home-like environments. Some hospices offer music or pet therapy and fill patient rooms with original artwork and fresh flowers.

Since the patient and his or her family members are considered the unit of care, hospice programs continue to support families and loved ones after the patient's death. Grief and bereavement counseling as well as support groups offer opportunities to express and resolve emotional concerns and share them with others.

Risks

The hospice approach emphasizes caring instead of curing, and some health professionals find this practice inconsistent with their previous education, experiences, beliefs, and traditions. Moreover, the involvement of complementary and alternative medicine practitioners may be unsettling for health professionals unaccustomed to interacting with these practitioners. For these reasons, family members and patients should make their wishes about hospice care known to their traditional medical care providers, so that all members of their healthcare team can work together with the same goals in mind.

Hospital-acquired infections

Definition

A hospital–acquired infection, also called a nosocomial infection, is one that is unrelated to the patient's original condition and first appears after

WWW.BOOKBAZ.IR

the patient is admitted to a hospital, nursing home, or other health care facility. Hospital–acquired infections can be bacterial, viral, or fungal.

Description

In the United States, the National Nosocomial Infections Surveillance (NNIS) System of the Centers for Disease Control and Prevention (CDC) tracks hospital–acquired infections. The CDC has estimated that about 10% of patients admitted to hospitals develop a nosocomial infection. In 2006, this amounted to close to 1.7 million patients and accounted for about 90,000 deaths.

Bacteria, viruses, fungi, or parasites can cause hospital–acquired infections. These microorganisms may already be present in the patient's body or may come from the environment, contaminated hospital equipment, health care workers, or other patients. Depending on the causal agents involved, an infection may start in any part of the body. A localized infection is limited to a specific part of the body and has local symptoms. For example, if a surgical wound in the abdomen becomes infected, the area of the wound becomes red, hot, and painful. A generalized infection is one that enters the bloodstream and causes general systemic symptoms such as **fever**, chills, low blood pressure, or mental confusion.

Hospital–acquired infections may develop from surgical procedures, catheters placed in the urinary tract or blood vessels, or from material from the nose or mouth that is inhaled into the lungs. The most common types of hospital–acquired infections are urinary tract infections (UTIs), **pneumonia**, and surgical wound infections.

Causes and symptoms

All hospitalized patients are susceptible to contracting a nosocomial infection. Some patients are at greater risk than others. Newborns, the elderly, and persons with compromised immune systems are more likely to get an infection. Other risk factors for getting a hospital–acquired infection are a long hospital stay, the use of indwelling catheters, failure of health care workers to wash their hands, and overuse of **antibiotics**.

Any type of invasive procedure can expose a patient to the possibility of infection. Common causes of hospital–acquired infections include:

- urinary bladder catheterization
- respiratory procedures
- surgery and wounds
- intravenous (IV) procedures

Urinary tract infection (UTI) is the most common type of hospital–acquired infection accounting for 32% of reported cases. Most hospital–acquired UTIs happen after **urinary catheterization**. Catheterization is the placement of a catheter through the urethra into the urinary bladder. This procedure is done to empty urine from the bladder, relieve pressure in the bladder, measure urine in the bladder, put medicine into the bladder, or for other medical reasons.

The healthy urinary bladder is sterile, which means it does not have any harmful bacteria or other microorganisms in it. There may be bacteria in or around the urethra but they normally cannot enter the bladder. A catheter can pick up bacteria from the urethra and allow them into the bladder, causing an infection to start.

Bacteria from the intestinal tract are the most common type to cause UTIs. Patients with poorly functioning immune systems, such as those with **AIDS** or who are taking antibiotics, are also at risk for infection by a fungus called *Candida*.

Pneumonia accounts for about 15% of hospital–acquired infections. Bacteria and other microorganisms are easily brought into the throat by respiratory procedures commonly done in the hospital. The microorganisms come from contaminated equipment or the hands of health care workers. Some of these procedures are respiratory intubation, suctioning of material from the throat and mouth, and mechanical ventilation. The introduced microorganisms quickly colonize the throat area. This means that they grow and form a colony, but do not yet cause an infection. Once the throat is colonized, it is easy for a patient to inhale the microorganisms into the lungs.

Patients who cannot **cough** or gag very well are most likely to inhale colonized microorganisms into their lungs. Some respiratory procedures can keep patients from gagging or coughing. Patients who are sedated or who lose consciousness may also be unable to cough or gag. The inhaled microorganisms grow in the lungs and cause an infection that can lead to pneumonia.

Surgical procedures increase a patient's risk of getting an infection in the hospital and account for about 22% of nosocomial infections. Surgery directly invades the patient's body, giving bacteria a way into normally sterile parts of the body. An infection can be acquired from contaminated surgical equipment or from health care workers. Following surgery, the surgical wound can become infected. Other **wounds** from **trauma**, **burns**, and **ulcers** may also become infected.

Many hospitalized patients need a steady supply of medications or nutrients delivered to their bloodstream. An intravenous (IV) catheter is placed in a vein and the medication or other substance is infused into the vein. Bacteria transmitted from the surroundings, contaminated equipment, or health care workers' hands can invade the site where the catheter is inserted. A local infection may develop in the skin around the catheter. Bacteria also can enter the blood through the vein and cause a generalized infection. Infections of the bloodstream account for about 14% of hospital–acquired infections. The longer a catheter is in place, the greater the risk of infection.

Other hospital procedures that put patients at risk for nosocomial infection are gastrointestinal procedures, obstetric procedures, and **kidney dialysis**.

In recent years, hospitals have had increasingly to contend with the development of antibiotic–resistant strains of bacteria. In fact, some organisms may be resistant to multiple antimicrobial agents (MDROs). Years of overprescribing and misuse of antibiotics and the increased use of antibiotics in the production of meat and milk have resulted in the emergence of strains of bacteria that are resistant to many antibiotics. A bacterium is considered resistant when it can no longer be treated effectively using antibiotics that are commonly prescribed for that type of infection.

Methicillin–resistant *Staphylococcus aureus*. is a strain of staph bacteria that is resistant to the antibiotic methicillin and other common antibiotics that normally control staph infections. Although this strain of staph has existed in hospitals for years, in the 1990s, MRSA began appearing in places other than hospitals. By 2007, two forms of MRSA were recognized, hospital–acquired MRSA (HA–MRSA) and community–acquired MRSA (CA–MRSA). Symptoms of a MRSA infection are similar to other staph infection symptoms, only MRSA is much more dangerous and has a much higher mortality rate because treatment with common antibiotics does not kill the bacterium.

Risk factors for acquiring HA–MRSA include hospitalization, especially in patients who need intravenous lines, feeding tubes, and catheters; residence in a nursing home; and recent treatment with certain antibiotics including the fluoroquinolone antibiotics ciprofloxacin (Cipro), ofloxacin (Floxin, Tarivid), levofloxacin (Levaquin, Elequine), and cephalosporin (Keflex). The Association of Professionals in **Infection Control** and Epidemiology estimates that in 2007 1.2 million hospital patients were infected with MRSA and about 423,000 were healthy carriers (i.e., they showed no symptoms) of the bacteria.

Fever is often the first sign of infection. Other symptoms and signs of infection are rapid breathing, mental confusion, low blood pressure, reduced urine output, and a high **white blood cell count**.

Patients with a UTI may have **pain** when urinating and blood in the urine. Symptoms of pneumonia may include difficulty breathing and coughing. A localized infection causes swelling, redness, and tenderness at the site of infection.

Diagnosis

An infection is suspected any time a hospitalized patient develops a fever that cannot be explained by a known illness. Some patients, especially the elderly, may not develop a fever. In these patients, the first signs of infection may be rapid breathing or mental confusion.

Diagnosis of a hospital–acquired infection is based on:

- symptoms and signs of infection
- examination of wounds and catheter entry sites
- review of procedures that might have led to infection
- laboratory test results

A complete **physical examination** is conducted in order to locate symptoms and signs of infection. Wounds and the skin where catheters have been placed are examined for redness, swelling, or the presence of pus or an **abscess**. The physician reviews the patient's record of procedures performed in the hospital to determine if any posed a risk for infection.

Laboratory tests are done to look for signs of infection. A **complete blood count** can reveal if the white blood cell count is high. White blood cells are immune system cells that increase in numbers in response to an infection. White blood cells or blood may be present in the urine when there is a UTI.

Cultures of blood, urine, sputum, other body fluids, or tissue are done to look for infectious microorganisms. If an infection is present, it is necessary to identify the microorganism so the patient can be treated with the correct medication. A sample of the fluid or tissue is placed in a special medium that bacteria grow in. Other tests can also be done on blood and body fluids to look for and identify bacteria, fungi, viruses, or other microorganisms responsible for an infection.

If a patient has symptoms suggestive of pneumonia, a chest x ray is done to look for infiltrates of white blood cells and other inflammatory substances in the

WWW.BOOKBAZ.IR

KEY TERMS

Abscess—Localized collection of pus in any part of the body that is surrounded by swelling.

Antibiotic—A drug used to treat infections caused by bacteria and other microorganisms.

Antibiotic–resistant—Microorganisms that continue to multiply although exposed to antibiotics.

Antimicrobial agent—A substance that kills microorganisms such as bacteria or mold, or stops them from growing and causing disease.

Bacterium—A single–celled microorganism that can be seen only through a microscope. Many bacteria cause disease.

Immune system—The integrated body system of organs, tissues, cells, and cell products such as antibodies that protects the body from foreign organisms or substances.

Multidrug–resistant organisms (MDROs)—Bacteria that are resistant to one or more classes of antimicrobial agents and usually are resistant to all but one or two commercially available antimicrobial agents.

Pus—A generally viscous, yellowish–white fluid formed in infected tissue, consisting of white blood cells, cellular debris, and dead tissue.

lung tissue. Samples of sputum can be studied with a microscope or cultured to look for bacteria or fungi.

Treatment

Once the source of infection is identified, the patient is treated with antibiotics or other medication that kills the responsible microorganism. Many different antibiotics are available that are effective against different bacteria. Some common antibiotics are penicillin, **cephalosporins**, **tetracyclines**, and erythromycin. More and more commonly, some types of bacteria are becoming resistant to the standard antibiotic treatments. When this happens, a different, more powerful antibiotic must be used. Two strong antibiotics that have been effective against resistant bacteria are vancomycin and imipenem, although some bacteria are developing resistance to these antibiotics as well.

Fungal infections are treated with antifungal medications. Examples of these medications are amphotericin B, nystatin, ketoconazole, itraconazole, and fluconazole.

A number of **antiviral drugs** have been developed that slow the growth or reproduction of viruses. Acyclovir, ganciclovir, foscarnet, and amantadine are examples of antiviral medications.

Prognosis

Hospital–acquired infections are serious illnesses that cause death in about 1% of cases. Rapid diagnosis and identification of the responsible microorganism is necessary, so treatment can be started as soon as possible.

Prevention

Hospitals and other health care facilities have developed extensive infection control programs to prevent nosocomial infections. These programs focus on identifying high–risk procedures and other possible sources of infection. High–risk procedures such as urinary catheterization should be performed only when necessary and catheters should be left in for as little time as possible. Medical instruments and equipment must be properly sterilized to ensure they are not contaminated. Frequent hand washing by health care workers and visitors is necessary to avoid passing infectious microorganisms to hospitalized patients. In 2003, the Joint Commission on Accreditation of Health care Organizations (JCAHO) announced it would make prevention of nosocomial infections a major goal for future years. JCAHO, the body that inspects hospitals for quality and accredits them accordingly, issued an alert stating that hospital–acquired infections are seriously underreported. In 2005, Pennsylvania and Florida became the first states to require hospitals to report data on hospital–acquired infections. Since then, many other states have passed similar legislation. Increasingly, lawsuits have been brought against hospitals by families of patients that have died from nosocomial infections. The problem of nosocomial infections has become more serious for hospitals to address as many bacteria are becoming resistant to antibiotics.

Antibiotics should be used only when necessary. Use of antibiotics creates favorable conditions for infection with the fungal organism *Candida*. Overuse of antibiotics is also responsible for the development of bacteria that are resistant to antibiotics.

HPV vaccination

Definition

HPV vaccination is the administration of a vaccine to protect against the two or four most dangerous of the more than 40 strains of sexually transmitted **human papillomavirus** (HPV) infection.

Description

In June 2006, the Advisory Committee on Immunization Practices (ACIP) voted to recommend the first vaccine developed to prevent **cervical cancer** and other diseases in females caused by certain types of HPV. This vaccine, Gardasil, protects against four HPV types (types 6, 11, 16, and 18), which together cause 70% of cervical cancers and 90% of **genital warts**. The Food and Drug Administration (FDA) licensed this vaccine for use in girls and women between the ages of 9 and 26 years and later licensed its use in boys and men of the same age.

HPV vaccine Gardasil is the only approved vaccine for males. The vaccine is recommended for males starting at age 11 or 12 through age 21. **Vaccination** is especially important for gay and bisexual men, including those with HIV infection, and is recommended up to age 26 for these two groups. Although the vaccine is safe for all males up to age 26, it is most effective if it is given before a boy becomes sexually active.

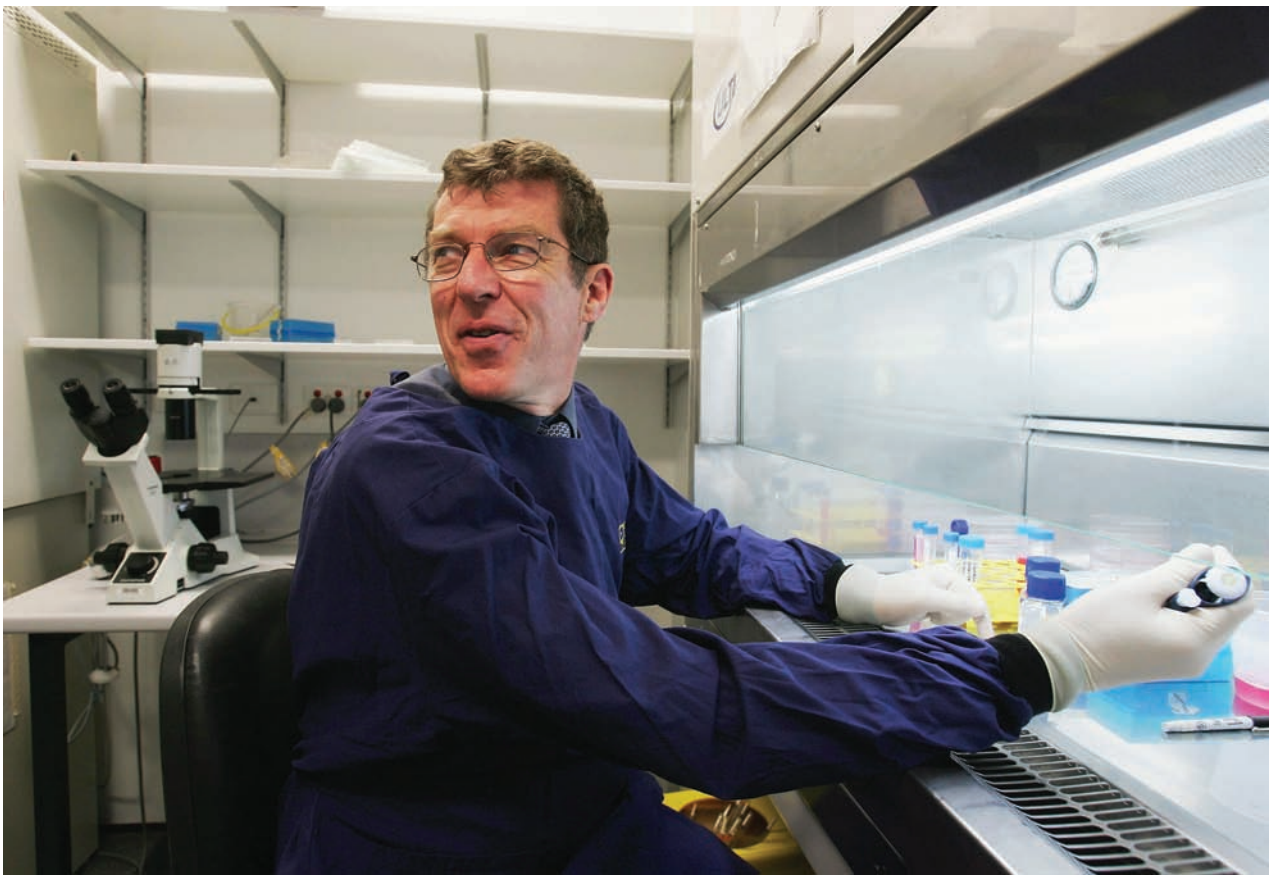
In 2009, drug manufacturer GlaxoSmithKline released a second HPV vaccine, Cervarix, only for females. This HPV vaccine is a bivalent vaccine, meaning it protects against HPV infection from two HPV types (types 16 and 18) that can cause precancerous and cancerous tumors of the cervix. Cervarix does not protect against genital **warts**. As of 2014, Cervarix had been approved by the FDA for use only in females ages 9–26 years. For girls fully immunized before they become sexually active, the vaccine prevents almost 100% of the diseases caused by the two types of HPVs targeted by the vaccine. Most health insurance plans will pay for HPV vaccination.

Purpose

In the 2010s, HPV infections are the most common **sexually transmitted infections** (STI) in the United States. Approximately 20 million Americans were infected with HPV as of 2013, and another 6 million people were likely to become newly infected each year. The Centers for Disease Control and Prevention (CDC) estimated that more than 80% of American women would contract at least one strain of genital HPV by age 50. As far as was known in 2014, men and women are at equal risk of being infected with HPV, as are members of all races and ethnic groups.

HPV infection has been linked to oropharyngeal cancer and cancers of the anus, vulva, vagina, and penis. Other types of HPV can cause genital warts in both males and females or warts in the upper respiratory tract. The HPV vaccines work by preventing the

WWW.BOOKBAZ.IR



Professor Ian Frazer, inventor of Gardasil, at work in a bio medical laboratory at the Princess Alexandra Hospital August 12, 2005 in Brisbane, Australia. *(Jonathan Wood/Getty Images)*

most common types of HPV that cause cervical cancer and genital warts.

In terms of specific illnesses associated with HPV, the American Cancer Society estimated 12,360 women the United States would be diagnosed with cervical cancer in 2014 and 4,020 women would die of the disease. Cervical cancer rates are much higher in other parts of the world, especially in developing countries. Another 3,179 women would be diagnosed with cancer of the vagina in 2014, whereas 1,640 men would be diagnosed with cancer of the penis, and a total of 7,210 men and women would be diagnosed with **anal cancer**. Men infected with HPV are at risk of developing penile and anal cancer. The risk of gay and bisexual men developing HPV-related cancers is 17 times higher than the risk for strictly heterosexual men.

Recommended dosage

Gardasil is given as three injections to both males and females, the first shot at around age 11 or 12, ideally well before an individual becomes sexually active. Cervarix is given only to girls on the same schedule. The second shot is given one to two months after the first, and the final shot is given six months after the first. All three shots are necessary to provide full protection. Both vaccines are administered intramuscularly. It is important for children to be vaccinated before their first sexual contact (i.e., before they can be exposed to any HPV). For fully immunized individuals, the vaccine can prevent almost 100% of the diseases caused by the types of HPVs targeted by the vaccine. Children as young as 9 years old can receive the vaccine. The vaccine is also recommended for girls and women 13 through 26 years of age who did not receive it when they were younger and for boys and men through age 21 or age 26 for men who have sex with men.

Risks

Vaccines can occasionally cause allergic reactions, as can all medications. The risk of a vaccine causing

KEY TERMS

Cervical cancer—Cancer of the entrance to the uterus. The cervix is the lower, narrow part of the uterus.

Cervical cancer screening—Use of the Papanicolaou (Pap) smear test to detect cervical cancer in the early curable stage.

Intramuscularly—A medication given by needle into a muscle.

Pathogen—A disease-causing microorganism.

Quadrivalent vaccine—A vaccine that protects against four pathogens.

Virus—A microorganism smaller than a bacterium, which cannot grow or reproduce apart from a living cell. Viruses cause many common human infections and are also responsible for many rare diseases.

Wart—A raised growth on the surface of the skin or other organ.

serious harm is extremely small. Overwhelmingly, health practitioners recommend vaccination over the risk of contracting the disease against which it protects. However, a small subset of people should not get the HPV vaccine. These include:

- Anyone who has ever had a life-threatening allergic reaction to yeast, to any other component of HPV vaccine, or to a previous dose of HPV vaccine.
- Pregnant women. Adequate data are not available on the vaccine's safety for pregnant women and the developing fetus. Women who are breastfeeding may safely get the vaccine.
- Individuals with moderate or severe illnesses. These individuals should wait to be vaccinated until they recover.

Protection from HPV vaccine is expected to be long lasting. However, vaccinated women still need cervical cancer screening because the vaccine does not protect against all HPV types that cause cervical cancer, and it is still possible to contract genital warts.

Side effects

According to the CDC, the following problems may follow HPV vaccination:

- Pain at the injection site (8 people in 10)
- Redness or swelling at the injection site (1 person in 4)
- Mild fever (100°F/37.8°C) (1 person in 10)
- Itching at the injection site (1 person in 30)
- Moderate fever (102°F/38.9°C) (1 person in 65)

A small number of people receiving the HPV vaccine have experienced syncope (**fainting**) or seizures. People receiving the vaccine should be observed for 15 minutes after receiving each dose.

Interactions

The FDA has licensed the HPV vaccine as safe and effective. This vaccine has been tested around the world in thousands of people between the ages of 9 and 26 years with no serious interactions or side effects.

Some medicines may interact with HPV vaccine. Alkylating agents (e.g., cyclophosphamide), antimetabolites (e.g., fluorouracil, methotrexate), cytotoxics (e.g., cisplatin), or **corticosteroids** (e.g., prednisone) may decrease the HPV vaccine's effectiveness.

Human bite wounds

Definition

Human bite **wounds** occur due to purposeful bites, or when the mouth and teeth accidentally collide with another individual's skin (during an athletic event or a fight, for example). Human bites are very dangerous, due to the high risk of infections caused by rapid growth of bacteria in broken skin.

Description

Bites—animal and human—are responsible for about 1% of visits to emergency rooms. Bite injuries are more common during the summer months.

Closed-fist injury

In adults, the most common form of human bite is the closed-fist injury, sometimes called the "fight bite." These injuries result from the breaking of the skin over the knuckle joint when a person's fist strikes someone's teeth during a fight.

Causes and symptoms

In children, bite infections result either from accidents during play or from fighting. Most infected bites in adults result from fighting.

KEY TERMS

Antibiotic—A drug used to treat infections caused by bacteria and other microorganisms.

Bacteria—Single-celled microorganisms that can be seen only through a microscope. Many bacteria cause disease.

The infection itself can be caused by the very large number of bacteria that live in the normal human mouth. These include streptococci, staphylococci, anaerobic organisms, and *Eikenella corrodens*. Infections that begin less than 24 hours after the injury are usually produced by a mixture of organisms and can cause a necrotizing infection (causing the death of a specific area of tissue), in which tissue is rapidly destroyed. If a bite is infected, the skin will be sore, red, swollen, and warm to the touch.

Diagnosis

In most cases the diagnosis is made by an emergency room physician on the basis of the patient's history.

Because the human mouth contains a variety of bacteria, the physician will order a laboratory culture to choose the most effective antibiotic.

Treatment

Treatment involves surgical attention as well as medications. Because bites cause puncturing and tearing of skin rather than clean-edged cuts, they must be carefully cleansed. The doctor will wash the wound with water under high pressure and debride it. **Debridement** is the removal of dead tissue and **foreign objects** from a wound to prevent infection. If the bite is a closed-fist injury, the doctor will look for torn tendons or damage to the spaces between the joints. Examination includes x rays to check for bone **fractures** or foreign objects in the wound.

Doctors do not usually suture a bite wound because the connective tissues and other structures in the hand form many small closed spaces that make it easy for infection to spread. Emergency room doctors often consult surgical specialists if a patient has a deep closed-fist injury or one that appears already infected.

The doctor will make sure that the patient is immunized against **tetanus**, which is routine procedure for any open wound. Superficial wounds in low-risk areas may not require preventive antibiotic treatment, but more serious human bites to high-risk areas such as the hands should be treated with **antibiotics** to

avoid serious infection. Patients with closed-fist injuries may need inpatient treatment in addition to an intravenous antibiotic.

Prognosis

The prognosis depends on the location of the bite and whether it was caused by a child or an adult. Bites caused by children rarely become infected because they are usually shallow. Between 15% and 30% of bites caused by adults become infected, with a higher rate for closed-fist injuries.

Prevention

Prevention of human bite infections depends upon prompt treatment of any bite caused by a human being, particularly a closed-fist injury.

Human chorionic gonadotropin
see **Infertility drugs**

Human chorionic gonadotropin (hCG) pregnancy test

Definition

The most common test of **pregnancy** involves the detection of a hormone known as human chorionic gonadotropin (hCG) in a sample of blood or urine.

Purpose

The purpose of the hCG test is to determine whether a woman is pregnant. Shortly after a woman's egg is fertilized by a male's sperm and is implanted in the lining or the womb (uterus), the placenta begins to form. This structure helps nourish the developing new life. The placenta produces hCG, whose presence—along with other hormones—helps maintain the early stages of pregnancy. Because hCG is produced only by placental tissue and can be found in the blood or urine, it has become a convenient chemical test of pregnancy.

Description

After implantation, the level of detectable hCG rises very rapidly, approximately doubling in quantity every two days until a peak is reached between the sixth and eighth week of pregnancy. Over the next ten or more weeks, the quantity of hCG slowly decreases. After this point, a much lower level is sustained for the duration of the pregnancy. Detectable levels of this hormone may even persist for a month or two after delivery.

Blood tests for hCG are the most sensitive and can detect a pregnancy earlier than urine tests. Blood tests for hCG can also distinguish normal pregnancies from impending miscarriages or pregnancies that occur outside of the uterus (ectopic pregnancies).

If a woman misses her menstrual period and wants to know whether she may be pregnant, she can purchase one of many home pregnancy test kits that are available. Although each of these products may look slightly different and provide a different set of directions for use, each one detects the presence of hCG. This indicator contains chemical components called antibodies that are sensitive to a certain quantity of this hormone.

Precautions

Although home pregnancy tests may be advertised as having an accuracy of 97% or better, studies indicate that pregnancy tests performed in the home may incorrectly indicate that a woman is not pregnant (a false negative result) 25–50% of the time. Studies also indicate that false negative results usually occur when a woman fails to follow the package directions or tests too soon after a missed menstrual period. Waiting a few days after the missed period can increase the accuracy of the test. Blood and urine tests performed by a laboratory are 97–100% accurate in detecting pregnancy.

Preparation

Generally, no preparation is required for a pregnancy test given in a doctor's office.

Home pregnancy test kits can be divided into two basic types. One type involves the use of a wand-like

WWW.BOOKBAZ.IR

KEY TERMS

Human chorionic gonadotropin (hCG)—A hormone produced by the placenta during pregnancy.

Placenta—The organ that provides oxygen and nutrition from the mother to the fetus during pregnancy. The placenta is attached to the wall of the uterus and leads to the fetus via the umbilical cord.

Uterus—The hollow, muscular female organ that supports the development and nourishment of the unborn baby during pregnancy.

device that a woman must place into her urine stream for a brief period of time. The other type of kit involves the use of a cup, a dropper, and a wand or stick with a small well. The cup is used to collect the urine, and the dropper is used to transfer a specific number of drops into the well. Results may be displayed in a variety of ways, such as a color change. It is important to follow package directions very carefully (the techniques vary from brand to brand) and to read the results in the time specified.

Aftercare

A woman should notify her physician immediately if her home pregnancy test is positive. Pregnancy can then be confirmed with hCG urine or blood tests taken in the doctor's office and evaluated by laboratory personnel. If performed accurately, home pregnancy tests have been found to be highly reliable. However, the versions of these tests performed by qualified laboratory technologists are considered to be definitive. Often, such a test will produce positive results before a woman experiences symptoms or before a doctor's exam reveals signs of pregnancy.

Risks

Tests for hCG levels pose no direct risk to a woman's health. The main risk with a home pregnancy test is a false negative result, which may be lessened by following the manufacturer's instructions carefully and waiting several days after the expected menstrual period to test. A false negative result can cause a delay in seeking prenatal care, which can pose a risk to both the woman and the baby.

Results

In most cases, a positive result is an indication of pregnancy. However, false positive results may also occur. If a pregnancy test is performed within a month or two of a recent birth or **miscarriage**, it is possible to test positive for pregnancy since hCG may still be detected in a woman's urine. Sometimes positive pregnancy tests provide clues of an early miscarriage that might have otherwise gone unrecognized because it occurred before or just after a missed period. An **ectopic pregnancy** (one in which an embryo implants outside the uterus), certain types of masses (such as an ovarian tumor or a **hydatidiform mole**), and the use of some fertility drugs that contain hCG are among other possibilities behind false positive results.

Human leukocyte antigen (HLA) test

Definition

The human leukocyte antigen (HLA) test, also known as HLA typing or **tissue typing**, identifies antigens on the white blood cells (WBCs) that determine tissue compatibility for organ transplantation (that

is, histocompatibility testing). There are six loci on chromosome 6, where the genes that produce HLA antigens are inherited: HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP.

Unlike most blood group antigens, which are inherited as products of two alleles (types of gene that occupy the same site on a chromosome), many different alleles can be inherited at each of the HLA loci. These are defined by antibodies (antisera) that recognize specific HLA antigens, or by DNA probes that recognize the HLA allele. Using specific antibodies, 26 HLA-A alleles, 59 HLA-B alleles, 10 HLA-C alleles, 26 HLA-D alleles, 22 HLA-DR alleles, 9 HLA-DQ alleles, and 6 HLA-DP alleles can be recognized. This high degree of genetic variability (polymorphism) makes finding compatible organs more difficult than finding compatible blood for **transfusion**.

Purpose

HLA typing, along with ABO (blood type) grouping, is used to provide evidence of tissue compatibility. The HLA antigens expressed on the surface of the lymphocytes of the recipient are matched against those from various donors. Human leukocyte antigen typing is performed for kidney, bone marrow, liver, pancreas, and heart transplants. The probability that a transplant will be successful increases with the number of identical HLA antigens.

Graft rejection occurs when the immune cells (T-lymphocytes) of the recipient recognize specific HLA antigens on the donor's organ as foreign. The T-lymphocytes initiate a cellular immune response that result in graft rejection. Alternatively, T-lymphocytes present in the grafted tissue may recognize the host tissues as foreign and produce a cell-mediated immune response against the recipient. This is called graft-versus-host disease (GVHD), and it can lead to life-threatening systemic damage in the recipient. HLA testing is performed to reduce the probability of both rejection and GVHD.

HLA typing is also used along with **blood typing** and DNA tests to determine the parentage (that is, for paternity testing). The HLA antigens of the mother, child, and alleged father can be compared. When an HLA antigen of the child cannot be attributed to the mother or the alleged father, then the latter is excluded as the father of the child.

A third use of HLA testing called linkage analysis is based on the region where the HLA loci are positioned, the major histocompatibility complex (MHC), which contains many other genes located very close to the HLA loci. The incidence of crossover between HLA genes during fertilization of the egg by sperm is generally less than 1%. Consequently, the HLA antigens from all six loci are inherited together and segregate with many other genes located within the same region of chromosome 6. Many of the MHC-region genes are involved in immunological processes. As a result, alleles that are known to increase the chance of developing various autoimmune diseases have remained associated with specific HLA alleles. For example, 2% of people who have the HLA-B27 allele develop an arthritic condition of the vertebrae called **ankylosing spondylitis**. However, approximately nine out of ten white persons who have ankylosing spondylitis are positive for HLA-B27. Because of this association, the disease and this HLA type are linked. Thus, a person with

KEY TERMS

Allele—Types of genes that occupy the same site on a chromosome.

Ankylosing spondylitis—An inflammatory arthropathy (arthritis-like disorder) of the vertebral column and sacroiliac joints.

Antibody—A protein (immunoglobulin) produced by B-lymphocytes in response to stimulation by a specific antigen.

Antigen—A molecule, usually a protein, that elicits the production of a specific antibody or immune response.

Autoimmune disorder—A disorder caused by a reaction of an individual's immune system against the organs or tissues of its own body.

B-lymphocyte—A type of blood cell that is active in immune response.

Cornea—The transparent outer layer of the eye. It covers the iris and lens.

Histocompatibility testing—Testing of genotypes of a recipient and potential donor to see whether rejection would occur when tissues are transplanted.

Lymphocyte—A class of white blood cell that is responsible for the immune response to antigens.

Macrophage—A type of blood cell derived from monocytes that are stimulated by inflammation and stimulate antibody production.

Monocyte—A type of white blood cell produced in bone marrow.

Phenotype—A trait produced by a gene. For example, the specific HLA antigen(s) inherited for the HLA-A locus is the phenotype for that gene.

WWW.BOOKBAZ.IR

ankylosing spondylitis who is also HLA-B27 positive would have family with a much higher likelihood of developing ankylosing spondylitis than those who are not. Some notable autoimmune diseases that have a strong association with HLA antigens include Hashimoto's **thyroiditis** (an autoimmune disorder involving underproduction by the thyroid gland) associated with HLA-DR5; Graves' disease (an autoimmune disorder associated with overproduction by the thyroid gland), associated with HLA-B8 and Dw3; and hereditary **hemochromatosis** (excess iron stores), associated with HLA-A3, B7, and B14.

Description

The HLA gene products can be grouped into three classes. Class I consists of the products of the genes located on the HLA-A, HLA-B, and HLA-C loci. These HLA antigens are found on all nucleated cells. Class II molecules consist of antigens inherited as genes from the HLA-DR, HLA-DQ, and HLA-DP loci. These HLA antigens are normally found only on B-lymphocytes, macrophages, monocytes, dendritic cells, endothelial cells, and activated T-lymphocytes. Class III molecules are not evaluated in histocompatibility testing.

Because the HLA loci are closely linked, the HLA antigens are inherited as a group of six antigens called a haplotype. The probability of siblings having identical haplotypes is one in four. Therefore, siblings provide the opportunity for the best matches. They can donate bone marrow, a kidney, and a section of their livers, but they cannot donate other solid organs. Approximately 85% of transplants are organs from cadavers, and because the HLA antigens are so highly polymorphic, the chance of identical haplotypes decreases quickly.

Histocompatibility testing consists of three tests: HLA antigen typing (tissue typing), screening of the recipient for anti-HLA antibodies (antibody screen), and the lymphocyte crossmatch (compatibility test). HLA antigen typing may be performed by serological (blood fluid) or DNA methods. In either case, HLA typing of HLA-A, HLA-B, HLA-DR, and HLA-DQ antigens is performed for solid organ transplants. HLA typing of HLA-C antigens is also included when tissue typing is performed for bone marrow transplants.

The antibody screen is performed in order to detect antibodies in the recipient's serum that react with HLA antigens. The most commonly used method of HLA antibody screening is the microcytotoxicity test. If an antibody against an HLA antigen is present, it will bind to the cells. The higher the number of different HLA antibodies, the lower the probability of finding a compatible match.

The third component of a histocompatibility study is the crossmatch test. In this test, peripheral blood lymphocytes from the donor are separated into B and T lymphocyte populations. In the crossmatch, serum from the recipient is mixed with T-cells or B-cells from the donor. A positive finding indicates the presence of preformed antibodies in the recipient that are reactive against the donor tissues. An incompatible T-cell crossmatch contraindicates transplantation of a tissue from the T-cell donor.

Precautions

HLA testing is performed using WBCs. If possible, this test should be postponed if the patient has recently undergone a transfusion, because any WBCs from the transfusion may interfere with the tissue typing of the patient's lymphocytes.

Preparation

The HLA test requires a blood sample. There is no need for the patient to fast before the test.

Aftercare

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Risks

Risks for this test are minimal, but may include slight bleeding from the puncture site, **fainting** or feeling lightheaded after having blood taken, or hematoma (blood accumulating under the puncture site).

Results

HLA typing either by serologic (blood fluid) or DNA methods is reported as the phenotype for each HLA loci tested. The antibody screen test is reported as the percentage of panel reactive antibodies (PRA). The percent PRA is the number of wells reactive with the patient's serum expressed in percent. The crossmatch is reported as compatible or incompatible.

Tissue typing results for both donors and recipients and antibody screen results for recipients are submitted to the United Network for Organ Sharing (UNOS) database. The database searches all regional donors that are ABO-compatible for an HLA-identical match. If none is found, the database searches the national database for ABO compatible donors and

scores the match. A point system is used based upon several parameters, including the number of matching HLA loci, the length of time the recipient has been waiting, the recipient's age, and the PRA score.

Human papillomavirus

Definition

Human papillomavirus (HPV) infect humans and some animals. Of the 130 or so known strains of HPV, about 40 are sexually transmitted. Of these, six are responsible for the most common **sexually transmitted infections** (STIs). HPVs infect the skin and mucous membranes. In humans, the sexually transmitted strains can cause **genital warts**, precancerous changes in the tissues of the female vagina and cervix, **cervical cancer**, and **anal cancer** in men and women. A 2013 analysis of multiple research studies (a meta-analysis) also linked HPV infection with a threefold increase in the risk of developing **esophageal cancer**. Other non-sexually transmitted strains of HPV are responsible for **warts** on the soles of the feet (plantar warts), common warts on the hands, and flat warts on the face or legs.

Description

The family of HPVs includes a large number of genetically related viruses. Many of these cause warts, including the warts commonly found on the skin. Another group of HPVs infect the mucosal surfaces of the genitals, including the male penis and the female vagina, vulva, and cervix. Genital warts are caused by HPV types 1, 2, 6, 11, 16, and 18 and are transmitted by vaginal, anal, or oral sex. The incubation period

Prevalence of HPV and related diseases

Human papillomavirus (HPV): Approximately 79 million Americans are currently infected with HPV and another 14 million become infected each year. HPV is so prevalent that half of all sexually active men and women contract it at some point in their lives.

Genital warts: About 360,000 people of sexually active adults in the United States get genital warts each year.

Cervical cancer: On average, 10,000 women in the United States are diagnosed with cervical cancer each year.

Other cancers that can be caused by HPV:
(diagnosis estimates, 2014)

- Vulvar cancer (4,850 women per year)
- Vaginal cancer (3,170 women per year)
- Penile cancer (1,640 men per year)
- Anal cancer (5,550 women and 2,660 men per year)

SOURCE: Centers for Disease Control and Prevention, "Genital HPV Infection Fact Sheet." Available online at: http://www.cdc.gov/std/hpv/stdfact-hpv.htm#a5 (accessed September 8, 2014).

(Table by PreMediaGlobal. Reproduced by permission of Gale, a part of Cengage Learning.)

WWW.BOOKBAZ.IR

varies from one to six months. The HPV strains that cause warts are considered low risk because they do not cause cancer.

The second group of viruses, termed high-risk HPV types, is associated with the development of cervical cancer. Women infected with a high-risk virus are at increased risk for developing precancerous lesions in the cervix. Infection with these viruses is common in adolescents and women in their twenties. Most women who are infected do not develop cancer. Researchers are uncertain why some women do and others do not. It is possible that other viruses work together with HPVs to produce precancerous changes in tissue. The appearance of abnormal cells containing high-risk HPV types is seen most frequently in women over the age of 30 who have abnormal Pap smears. **Smoking**, the use of **oral contraceptives** for birth control for longer than five years, and suppression of the immune system are thought to be factors that may combine with HPV infection to lead to precancerous lesions in tissue.

The approximate percentages of cancers caused by high-risk types of HPV are as follows:

- cervical cancer: 100%
- anal cancer: 90%
- cancer of the vulva: 40%
- vaginal cancer: 40%
- oropharyngeal cancer: 12%
- oral cancer: 3%

It was not fully understood as of 2014 why most infections with high-risk HPV are of short duration, whereas a small percentage persist and eventually transform cervical cells to a state of cancerous growth.

Risk factors

Some people are at greater risk of sexually transmitted HPV than others. Those at greater risk include:

- men who have sex with other men
- women who have sex with bisexual men
- people with HIV or other diseases that weaken the immune system
- individuals younger than age 25
- people who have large numbers of sexual partners
- people in relationships with partners who have sex with many other people
- people who take drugs that suppress the immune system

Demographics

In the 2010s, HPV infections are the most common STI in the United States. Approximately 20 million Americans were infected with HPV as of 2013, and another 6 million people were likely to become newly infected each year. The Centers for Disease Control and Prevention (CDC) estimated that more than 80% of American women were likely to contract at least one strain of genital HPV by age 50. As far as was known, men and women are at equal risk of being infected with HPV, as are members of all races and ethnic groups.

In terms of specific illnesses associated with HPV, the American Cancer Society estimated 12,360 women in the United States would be diagnosed with cervical cancer in 2014 and 4,020 women would die of the disease. Cervical cancer rates were much higher in other parts of the world, especially in developing countries. Another 3,179 women would be diagnosed with cancer of the vagina, and 1,640 men would be diagnosed with cancer of the penis, and a total of 7,210 men and women would be diagnosed with anal cancer. Men infected with HPV are at risk of developing penile and anal cancer. The risk of gay and bisexual men developing HPV-related cancers is 17 times higher than the risk for strictly heterosexual men.

Causes and symptoms

Causes

The cause of a sexually transmitted HPV infection is one or more strains of HPV. The virus enters the body through small breaks in the skin surface or in the mucous membranes lining the genitals. In most cases, the body fights off the virus within a few weeks. In some people, however, HPV remains dormant in one of the lower layers of skin cells for a period ranging from a few weeks to three years. The virus becomes active and replicates (copies itself) when these cells mature and move to the surface of the skin. The virus affects the shape of the cells, leading to the formation of noticeable warts, precancerous changes in skin cells or cervical cells, or eventually cervical cancer. About 10% of women with high-risk HPV in the tissues of their cervix are likely to develop long-lasting HPV infections that put them at increased risk for cervical cancer.

Symptoms in adults

Symptoms of sexually transmitted HPV infection may include:

- Genital warts. These appear as bumps or clusters of fleshy outgrowths around the anus or on the genitals. Some may grow into large cauliflower-shaped

masses. Genital warts usually appear within weeks to months after sexual contact with an infected person. If left untreated, genital warts may go away, remain unchanged, or increase in size or number, but they will not turn into cancers. It is possible, however, for a person to be infected with a high-risk strain of HPV as well as one of the strains that cause genital warts; therefore, the appearance of genital warts does not necessarily mean that the person is not at risk of cervical cancer.

- Precancerous changes in the tissues of the female cervix. These are flat growths on the cervix and change to the cervical cells. They cannot be seen or felt by the infected woman.
- Cancer. High-risk strains of HPV can cause cancers of the mouth, throat, and possibly esophagus as well as cancers of the anal area and the genitals. These typically develop years after the initial infection.

Symptoms in children

In addition to producing precancerous lesions in some patients, HPV infections in women are a health concern because they can be transmitted to the respiratory tract of a baby during **childbirth**. This type of HPV infection may lead to a rare disorder known as juvenile-onset recurrent respiratory papillomatosis (JO-RRP) or laryngeal papillomatosis, in which papillomas or warts form in the child's airway, producing hoarseness or partial blockage of the windpipe. Although laryngeal papillomatosis can occur in HPV-infected adults, 60–80% of cases occur in children, most of them younger than three years.

Laryngeal papillomatosis is usually diagnosed by **laryngoscopy**. Surgery, whether traditional or **laser surgery**, is the usual treatment for JO-RRP, but the warts often recur and require additional surgery to remove them. In extreme cases, the patient may be given a **tracheotomy**, a procedure in which a hole is cut through the throat into the windpipe and a tube is inserted to keep the breathing hole open. Another treatment for the disorder is **photodynamic therapy** or PDT. In PDT, a special light-sensitive dye is injected into the patient's blood. The dye collects in the tumors rather than in healthy tissue. When bright light of a specific wavelength is shone on the throat, it destroys the tumors containing the dye.

Drug therapy often is given as adjuvant treatment for this disease. JO-RRP is a serious illness, leading to death in a significant number of affected children. In a very few cases, respiratory papillomatosis can lead to cancer as well as breathing difficulties.

KEY TERMS

Ablative—The surgical removal of lesions associated with HPV. The noun form of the word is ablation.

Biopsy—The removal of a small bit of tissue for diagnostic examination.

Cervical intra-epithelial neoplasia (CIN)—A precancerous condition in which a group of cells grows abnormally on the cervix but does not extend into the deeper layers of this tissue.

Cervix—The narrow neck or outlet of the uterus.

Cryotherapy—The use of liquid nitrogen or other forms of extreme cold to destroy tissue.

Epithelial—Of or relating to the epithelium, the layer of cells forming the epidermis of the skin and the surface layer of mucous membranes.

High-risk HPV type—A member of the HPV family of viruses that is associated with the development of cervical cancer and precancerous growths.

Pap test—A screening test for cervical cancer devised by Giorgios Papanikolaou (1883–1962) in the 1940s.

Photodynamic therapy (PDT)—A treatment for tumors in which a light-sensitive dye is injected into the blood (or skin) to be taken up selectively by the tumors. Light of a specific wavelength is then applied to the affected area to kill the tumors.

Topical—Referring to a type of medication applied directly to the skin or outside of the body.

Tracheotomy—A surgical procedure in which a hole is cut through the neck to open a direct airway through an incision in the trachea (windpipe).

Diagnosis

There are no blood, urine, or imaging tests to detect HPV infection. Sexually active women should be screened periodically for the presence of changes in the tissues of the cervix. The most common test is the Papanikolaou test or Pap smear, invented by a Greek physician in the 1940s. To perform a Pap smear, the doctor takes a small spatula to obtain cells from the outer surface of the cervix and smears the collected cells on a slide that is then examined in a laboratory for signs of any abnormal cells. If abnormal or questionable cells are found, the doctor may order an HPV DNA test, which can identify the DNA of 13 high-risk types of HPV in cells taken from the cervix.

WWW.BOOKBAZ.IR

There were no HPV screening tests for men as of 2014; however, some doctors suggested that anal Pap smears for men who have sex with men would be useful in early detection of anal cancer.

Since the incidence of latent and recurrent infections is high, it is essential for women to engage in safer sex practices to decrease the risk of spreading HPVs or becoming reinfected. Two vaccines effective against several of the HPV types most likely to cause genital warts or cervical cancer have been approved by the U.S. Food and Drug Administration (FDA).

Treatment

Patients with genital warts should never use over-the counter-preparations designed to remove common or flat warts from the hands or face. Doctors can treat genital warts with various medical or surgical techniques:

- Cryotherapy. Cryotherapy uses liquid nitrogen to freeze the warts. The dead tissue in the wart falls away from the skin beneath in about a week.
- Imiquimod. Imiquimod (Aldara) is a topical cream that gets rid of genital warts by stimulating the body's immune system to fight the virus that causes the warts.
- Podofilox. Podofilox (Condylox) is a topical medication available in liquid or gel form that destroys the wart tissue.
- Surgery. The doctor can remove the wart by drying it out with an electric needle and then scraping the tissue with a sharp instrument called a curette. Lasers can also be used to remove genital warts.

Low-grade precancerous changes in the tissue of the female cervix usually are not treated directly because most of them eventually go away on their own without developing into cancer. The woman should, however, see the doctor for follow-up Pap smears to make sure that the tissues are returning to normal. High-grade precancerous lesions are removed, usually by surgery, **cryotherapy**, electrocauterization, or laser surgery.

Since the incidence of latent and recurrent infections is high, the eradication of HPV is not always 100% effective. It is essential to be aware that HPV is a sexually transmitted disease, and women must engage in safer sex practices to decrease the risk of spreading the virus or becoming reinfected.

Prognosis

The prognosis of sexually transmitted HPV infections depends on the individual's age, number of sexual partners, gender, and the condition of his or her immune system. Women are significantly more likely than men to develop cancers following HPV infection. However, most people of either sex with normally functioning immune systems who are infected with HPV will clear the infection from their bodies within two years without treatment.

Prevention

In June 2006, the Advisory Committee on Immunization Practices (ACIP) voted to recommend the first vaccine developed to prevent cervical cancer and other diseases in females caused by certain types of HPV. This vaccine, Gardasil, protects against four HPV types (types 6, 11, 16, and 18), which together cause 70% of cervical cancers and 90% of genital warts. The FDA licensed this vaccine for use in girls and women between the ages of 9 and 26 years.

As of 2014, HPV vaccine Gardasil was the only approved vaccine for males. The vaccine is recommended for males starting at age 11 or 12 through age 21. **Vaccination** is especially important for gay and bisexual men, including those with HIV infection, and is recommended up to age 26 for these two groups. Although the vaccine is safe for all males up to age 26, it is most effective when given before a boy becomes sexually active.

Gardasil is given as three injections to both males and females, ideally, well before a individual becomes sexually active. The second shot is given one to two months after the first, and the final shot is given six months after the first. All three shots are necessary to provide full protection.

In 2009, drug manufacturer GlaxoSmithKline released a second HPV vaccine, Cervarix, only for females. This HPV vaccine is a bivalent vaccine, meaning it protects against HPV infection from two HPV types (types 16 and 18) that can cause precancerous and cancerous tumors of the cervix. Cervarix does not protect against genital warts. Cervarix was approved by the FDA for use only in females ages 9–26 years. For girls fully immunized before they become sexually active, the vaccine prevents almost 100% of the diseases caused by the two types of HPVs targeted by the vaccine.

The HPV vaccine is given as three injections, ideally well before a female becomes sexually active, usually around age 11 or 12, although it may be given as young as age 9. The second shot is given one to two months after the first, and the final shot is given six months after the first. All three shots are necessary to provide full protection. Protection is expected to be long lasting. However, vaccinated women still need cervical cancer screening because the vaccine does not protect against all HPV types that cause cervical cancer and because the vaccine is new enough that scientists do not know exactly how long full protection will last. Most health insurance plans pay for **HPV vaccination**.

Other preventive measures that people can take to lower their risk of HPV infection include:

- abstaining from sex or having sex only with an uninfected partner who is monogamous
- reducing the number of sexual partners
- using condoms regularly during sexual intercourse

Rebecca J. Frey, PhD
REVISED BY TISH DAVIDSON, AM

Human-potential movement

Definition

The human-potential movement is a term used for humanistic psychotherapies that first became popular in the 1960s and early 1970s. The movement emphasized the development of individuals through such techniques as encounter groups, sensitivity training, and primal therapy. Although the human-potential movement and humanistic therapy are sometimes used as synonyms, in reality, humanistic therapy preceded the human-potential movement and provided the movement's theoretical base. Humanistic therapy flourished in the 1940s and 1950s. Its theorists were mostly psychologists rather than medical doctors. They included Gordon Allport, Abraham Maslow, Everett Shostrom, Carl Rogers, and Fritz Perls.

The human-potential movement and humanistic therapy is distinguished by the following emphases:

- A concern for what is uniquely human rather than what humans share with other animals.
- A focus on each person's open-ended growth rather than reshaping individuals to fit society's demands.
- An interest in the here-and-now rather than in a person's childhood history or supposed unconscious conflicts.
- A holistic approach concerned with all levels of human being and functioning—not just the intellectual—including creative and spiritual functioning.
- A focus on psychological health rather than disturbance.

Purpose

The purpose of humanistic therapy is to allow a person to make full use of his or her personal capacities leading to self-actualization. Self-actualization requires the integration of all the components of one's unique personality. These elements or components of personality include the physical, emotional, intellectual, behavioral, and spiritual. The marks of a self-actualized person are maturity, self-awareness, and authenticity. Humanistic therapists think that most people—not only those with obvious problems—can benefit

WWW.BOOKBAZ.IR

from opportunities for self-development. Humanistic therapy uses both individual and group approaches.

Precautions

Psychotic patients, substance abusers, and persons with severe **personality disorders** or disorders of impulse control may not be appropriate for treatment with humanistic methods.

Description

Humanistic approaches to individual treatment usually follow the same format as other forms of outpatient counseling. Therapists may be medical doctors, nurses, psychologists, social workers, or clergy. Humanistic group treatment formats are flexible, and a wide range of treatment methods are used, ranging from encounter groups and therapy groups to assertiveness training and consciousness-raising groups. In addition, the humanistic tradition has fostered the publication of self-help books for people interested in psychological self-improvement.

Risks

The chief risks include the reinforcement of self-centered tendencies in some patients and the dangers resulting from encounter groups led by persons without adequate training. Poorly led encounter groups can be traumatic to persons with low tolerance for confrontation or "uncovering" of private issues.

Results

The anticipated outcome of humanistic therapy is a greater degree of personal wholeness, self-acceptance, and exploration of one's potential. In group treatment, participants are expected to grow in interpersonal empathy and relationship skills. However, there have been few controlled studies to determine the reasonableness of these expectations.

Hunger and undernutrition

Definition

Hunger is the lack of availability of food in a country. Over time, hunger leads to undernutrition, which is the result of extremely inadequate intake of calories, protein, or micronutrients. Although undernutrition and **malnutrition** often are used interchangeably, malnutrition is a more inclusive term that includes overnutrition.

Demographics

Undernutrition affects 925 million people in the world. This number is broken down geographically as follows:

- Asia and the Pacific—578 million
- Sub–Saharan Africa—239 million
- Latin America and the Caribbean—53 million
- Near East and North Africa—37 million
- Developed nations—19 million

The United Nations Children's Fund (UNICEF) estimates that about 195 million children have stunted growth as a direct result of undernutrition. Of these, about 90% are in Africa and Asia. India has the largest absolute number of stunted children, while Afghanistan has the highest percentage of stunted children. Undernutrition is uncommon in the developed world, but the British **Nutrition** Foundation estimates that about two million people in the United Kingdom are undernourished. Undernutrition has the most severe impact on children under age five.

Undernutrition in children is much less common in the United States than in developing countries. Estimates suggest that only about 1% of all children in the United States experience undernutrition. The highest-risk children in the United States are those living in homeless shelters, where an estimated 10% of children are undernourished. Estimates also suggest that one in every seven elderly individuals in the United States consumes fewer than 1,000 calories per day and is undernourished.

Approximately half of the hungry people in the world live in rural communities with land that tends to be subject to natural disasters. One-fifth of hungry people live in shanty towns on the edges of larger cities in developing nations.

Description

There is enough food produced to feed everyone in the world 2,720 kilocalories each day. However,

some people do not have access to enough food in their region, while others cannot afford to purchase food. Poverty is the primary cause of hunger in the world.

Undernutrition is a serious problem in developing countries, especially in children under age five years. It is estimated that 146 million children in developing nations weigh less than their ideal weight because they suffer from hunger, on either a short- or long-term basis. Undernutrition can begin before a baby is born. Deficiencies in calories, protein, **minerals**, and/or **vitamins** often affect the fetus during **pregnancy** because the mother does not consume enough calories and micronutrients. This often results in the delivery of a low-birthweight baby. According to the World Health Organization (WHO), low-birthweight accounts for about 60% of deaths in newborns in developing countries or 3.3% of all child deaths.

Undernutrition frequently continues into early childhood. It is estimated that children who are not properly nourished are sick 160 days out of the year. There is a strong relationship between undernutrition and failure to survive. Undernutrition intensifies the diseases a child may develop, such as **measles**. Children might not directly starve to death from undernutrition, although some do die of disorders such as marasmus, which is a severe deficiency in calories and protein. Instead, undernourished children tend to have weak immune systems that leave them highly susceptible to common diseases such as **diarrhea**, **pneumonia**, **malaria**, and measles, all of which are common in the developing world. Often, undernourished children go through a downward cycle of repeated disease and recovery before they die; if they do survive, this cycle exacts a heavy toll on their development. Exact figures are difficult to obtain from developing countries, but estimates suggest that maternal and child undernutrition is the cause of 3–5 million deaths annually. Zinc and **vitamin A** deficiency are the most common micronutrient deficiencies, while iron and iodine deficiencies also contribute to undernutrition.

A critical window for development exists between birth and age two years. Even when children survive these critical years, the effects of undernutrition remain. Often, these children are stunted (short stature) or wasted (seriously underweight). In addition to physical effects, undernutrition can restrict a child's mental development.

Undernutrition in the elderly is a greater problem in the United States than undernutrition in children. Declining appetite, limited funds, difficulty in preparing and eating food, and disease all contribute to undernutrition in the elderly. Elderly people living in nursing homes or hospitalized for prolonged periods are at high risk for undernutrition. Individuals of any age who have had **gastric bypass** surgery may experience undernutrition unless they take prescribed vitamin and mineral supplements.

KEY TERMS

Micronutrients—Minerals and vitamins needed in small quantities to maintain health (e.g., iodine).

Stunting—A height more than two standard deviations from the median height for the age in the reference population.

Wasting—Weight more than two standard deviations below that of the median weight for the reference population.

Risk factors

Risk factors for undernutrition include inadequate food supply (e.g., famine), inadequate variety of food (i.e., food does not contain all the required micronutrients), living in a war zone, poverty, HIV/AIDS, low maternal status, poor **breastfeeding** habits, and cultural attitudes (e.g., boy infants may be fed more than girl infants).

Homelessness is a major cause of undernutrition in the United States, as is **alcoholism**. Diseases such as depression or other mental illness can cause individuals to stop eating or to refuse to eat a variety of foods. Certain medications can also inhibit the uptake of nutrients from the digestive system, resulting in undernutrition. Certain diseases, such as some cancers and **AIDS**, can cause the body to increase the amount of calories used, resulting in severe wasting, called cachexia. **Protein-energy malnutrition** (PEM) is the most dangerous level of undernutrition caused by a shortage of calories and protein.

Causes and symptoms

The root cause of undernutrition is inadequate intake of calories, protein, and micronutrients. Secondary causes are the same as the risk factors previously described. Food shortages, particularly in developing countries, contribute to hunger. Drought is the most common cause of food shortage. Human causes of food shortages accounted for 15% of the problem prior to 1992. Since that year, human causes, such as war, have risen to the point where they account for 35% of food shortages.

WWW.BOOKBAZ.IR

Symptoms of undernutrition in children include low birth weight, stunting, wasting, low energy level, slowed physical development, impaired mental development, and frequent serious illnesses. In the elderly, undernutrition can cause weight loss, thinning and drying of the skin, hair loss, constantly feeling cold, confused thinking, frequent falls, and frequent infections. These symptoms often go unrecognized and are attributed to a general decline due to **aging**.

Diagnosis

Examination

Diagnosis is most often made by examination and by comparing the height and weight of the individual to the median height and weight of the reference population. The physician will review drugs the individual is taking and will ask questions about alcohol and food consumption.

Tests

A **complete blood count** (CBC) generally is done to assess the individual's general health and to look for signs of infections. Blood tests may be done to measure the amount of albumin in the blood. Albumin is a blood protein that decreases when there is an inadequate amount of protein in the diet. Additional tests may be done when a specific vitamin or **mineral deficiency** is suspected.

Treatment

The only treatment for undernutrition is to increase calories and protein and to replace the micronutrients missing from the diet. In healthcare settings, such as a nursing home or hospital, this can be done in consultation with a registered dietitian. Long-term success in reducing undernutrition generally requires overcoming the barriers that prevent the individual from getting enough calories and enough food variety. This may involve:

- treating any underlying disease or mental condition contributing to the undernutrition
- overcoming barriers to food preparation, for example, by enrolling the individual in Meals on Wheels
- providing a wide range of nutritious food through meals for the homeless, the establishment of inner-city farmers's markets, or providing transportation to local food banks
- using drugs to stimulate the appetite
- enrolling individuals in food-support programs, such as Women Infants and Children (WIC), the Supplementary Nutrition Program (SNAP, formerly food stamps), and the Federal School Lunch program in the United States

In 2010, the World Health Organization studied the use of Ready to Use Therapeutic Foods (RUTF) in chidden who suffered undernutrition during treatment for HIV/AIDS. The researchers concluded that the use of RUTF was associated with a reduction in undernutrition.

Individuals who cannot eat, for example, those who cannot swallow because they have had a **stroke**, may be fed through a tube inserted into the nose and down the esophagus to the stomach. Individuals who do not absorb enough nutrients from the digestive tract may be fed intravenously (total **parenteral nutrition**). Both of these feeding methods have drawbacks and potentially serious side effects.

Prognosis

Some early effects of undernutrition cannot be reversed. Consistent undernutrition before birth and during the first five years of life often leads to childhood death. In survivors, it has permanent physical and developmental effects. Even if the child later receives adequate nutrition, he or she may remain short of stature and have permanent cognitive deficits. Undernutrition during pregnancy can lead to **miscarriage**, premature delivery, a-low birthweight baby, maternal susceptibility to disease, and maternal death. Undernutrition in the elderly results in more frequent and more severe illness and infection.

Prevention

The problem of preventing undernutrition is complex. Many international aid agencies work to prevent undernutrition, especially in children. Their goal is to eventually help developing countries develop adequate food resources for the entire population. To do this, they must overcome food delivery, storage, and distribution problems; regional warfare; poverty; illiteracy; and cultural attitudes. UNICEF and WHO have made reducing child undernutrition one of their priorities for the twenty-first century.

Exclusive breastfeeding for at least six months with supplemental breastfeeding until age two is recommended for all babies. This is especially important in developing countries where supplies of clean water and adequate infant food are limited. According to WHO, appropriately breastfed children in developing

countries are six times more likely to survive to age five than those who are not breastfed.

In the United States, treating homelessness, alcoholism, and drug abuse, as well as educating individuals about food security programs that are available to them, are the most effective ways of preventing undernutrition.

Huntington's chorea *see* **Huntington's disease**

Huntington's disease

Definition

Huntington's disease (HD) is an inherited, progressive, neurodegenerative disease causing uncontrolled physical movements and mental deterioration. The disease was discovered by George Huntington of Pomeroy, Ohio, who first described a hereditary movement disorder.

Demographics

HD is estimated to occur in the United States at a rate of 4.1–8.4 cases per 100,000 people. In most European countries, prevalence ranges from 1.63–9.95 per 100,000 people. It is lower in Finland and Japan (less than 1 case per 100,000 people). Pockets of isolated populations with western European ancestors exist where the prevalence is higher. For example, these include the region of lake Maracaibo in Venezuela (700 per 100,000 people), the island of Mauritius (46 per 100,000 people), and Tasmania (17.4 per 100,000 people). HD is a disease that affects males and females equally.

The mean age at HD onset ranges from 35–44 years. HD onset in patients younger than 10 years and older than 70 years is rare. Modifying genes and environmental factors are thought to influence the age of onset. For example, the Venezuelan age of onset (34.35 years) is on average higher than that of Americans (37.47 years) and Canadians (40.36 years).

Description

HD is also called Huntington chorea, from the Greek word for "dance," referring to the involuntary movements that develop as the disease progresses. It is occasionally referred to as "Woody Guthrie disease" for the U.S. folk singer who died from it. HD causes

WWW.BOOKBAZ.IR

progressive loss of cells in areas of the brain responsible for some aspects of movement control and mental abilities. A person with HD gradually develops abnormal movements and changes in cognition (thinking), behavior and personality.

Risk factors

Children of a parent who carries the gene responsible for HD have a 50% chance of inheriting the abnormal gene.

Causes and symptoms

Mutations in the HTT gene cause HD. This gene provides instructions for making a protein called huntingtin, a protein that is believed to play an important role in the development of brain neurons. The HTT mutation involves lengthening a DNA segment known as a CAG trinucleotide repeat. The extra building blocks in the huntingtin gene cause the protein that is made from it to contain an extra section. It is currently thought that this extra protein section interacts with other proteins in brain cells where it occurs, and that this interaction ultimately leads to cell death.

The HD gene is a dominant gene, meaning that only one copy of it is needed to develop the disease. HD affects both males and females. The gene may be inherited from either parent, who will also be affected by the disease. A parent with the HD gene has a 50% chance of passing it on to each offspring. The chances of passing on the HD gene are not affected by the results of previous pregnancies.

The symptoms of HD fall into three categories: motor or movement symptoms, personality and behavioral changes, and cognitive decline. The severity and rate of progression of each type of symptom can vary from person to person.

Early motor symptoms include restlessness, twitching and a desire to move about. Handwriting may become less controlled, and coordination may decline. Later symptoms include:

- Dystonia, or sustained abnormal postures, including facial grimaces, a twisted neck, or an arched back.
- Chorea, in which involuntary jerking, twisting or writhing motions become pronounced.
- Slowness of voluntary movements, inability to regulate the speed or force of movements, inability to initiate movement, and slowed reactions.
- Difficulty speaking and swallowing due to involvement of the throat muscles.
- Localized or generalized weakness and impaired balance ability.
- Rigidity, especially in late–stage disease.

Personality and behavioral changes include depression, irritability, **anxiety**, and apathy. The person with HD may become impulsive, aggressive, or socially withdrawn.

Cognitive changes include loss of ability to plan and execute routine tasks, slowed thought, and impaired or inappropriate judgment. Short–term **memory loss** usually occurs, although long–term memory is usually not affected. The person with late–stage HD usually retains knowledge of his environment and recognizes family members or other loved ones, despite severe cognitive decline.

Diagnosis

Examination

Diagnosis of HD begins with a detailed medical history, and a thorough physical and **neurological exam**. Family medical history is very important as HD is inherited.

Tests

Magnetic resonance imaging (MRI) or computed tomography scan (CT scan) imaging may be performed to look for degeneration in the basal ganglia and cortex, the brain regions most affected in HD.

A genetic test is available for confirmation of the clinical diagnosis. In this test, a small blood sample is taken, and DNA from it is analyzed to determine the CAG repeat number. A person with a repeat number of 30 or below will not develop HD. A person with a repeat number between 35 and 40 may not develop the disease within their normal life span. A person with a very high number of repeats (70 or above) is likely to develop the juvenile–onset form. An important component of **genetic testing** is extensive **genetic counseling**.

Prenatal testing is also available. A person at risk for HD may obtain fetal testing without determining whether she herself carries the gene. This test, also called a linkage test, examines the pattern of DNA near the gene in both parent and fetus, but does not analyze for the triple nucleotide repeat (CAG). If the DNA patterns do not match, the fetus can be assumed not to have inherited the HD gene, even if present in the parent. A pattern match indicates the fetus probably has the same genetic makeup of the at–risk parent.

KEY TERMS

Chorea—Involuntary writhing movements.

Cognition—The mental activities associated with thinking, learning, and memory.

Computed tomography (CT) scan—An imaging procedure that produces a three–dimensional picture of organs or structures inside the body, such as the brain.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Heimlich maneuver—An action designed to expel an obstructing piece of food from the throat. It is performed by placing the fist on the abdomen, underneath the breastbone, grasping the fist with the other hand (from behind), and thrusting it inward and upward.

Neurodegenerative—Relating to degeneration of nerve tissues.

Neuron—A cell that is specialized to conduct nerve impulses.

Treatment

Traditional

There is no cure for HD, nor any treatment that can slow the rate of progression. Treatment is aimed at reducing the disability caused by the motor impairments, and treating behavioral and emotional symptoms.

Physical therapy is used to maintain strength and compensate for lost strength and balance. Stretching and range of motion exercises help minimize contracture, or muscle shortening, a result of weakness and disuse. The physical therapist also advises on the use of mobility aids such as walkers or wheelchairs.

Occupational therapy is used to design compensatory strategies for lost abilities in the activities of daily living, such as eating, dressing, and grooming. The occupational therapist advises on modifications to the home that improve safety, accessibility, and comfort.

Difficulty swallowing may be lessened by preparation of softer foods, blending food in an electric blender, and taking care to eat slowly and carefully. Use of a straw for all liquids can help. The potential for **choking** on food is a concern, especially late in the disease progression. Caregivers should learn the use of the **Heimlich maneuver**. In addition, passage of food into the airways increases the risk for **pneumonia**. A gastric feeding tube may be needed, if swallowing becomes too difficult or dangerous.

Speech difficulties may be partially compensated by using picture boards or other augmentative communication devices. Loss of cognitive ability affects both speech production and understanding. A speech–language pathologist can work with the family to develop simplified and more directed communication strategies, including speaking slowly, using simple words, and repeating sentences exactly.

Drugs

Motor symptoms may be treated with drugs, although some studies suggest that anti–chorea treatment rarely improves function. Chorea (movements caused by abnormal muscle contractions) can be suppressed with drugs that deplete dopamine, an important brain chemical regulating movement. As HD progresses, natural dopamine levels fall, leading to loss of chorea and an increase in rigidity and movement slowness. Treatment with L–dopa (which resupplies dopamine) may be of some value. Frequent reassessment of the effectiveness and appropriateness of any drug therapy is necessary. In August 2008 the Food and Drug Administration (FDA) approved tetrabenazine to treat Huntington's chorea, making it the first drug approved for use in the United States to treat HD.

Early behavioral changes, including depression and anxiety, may respond to drug therapy. Maintaining a calm, familiar, and secure environment is useful as the disease progresses. Support groups for both patients and caregivers form an important part of treatment.

Alternatives

As of 2014, 857 clinical trials for the treatment of HD were being sponsored by the National Institutes of Health (NIH) and other agencies. A few examples include:

- The study of early brain and behavioral changes in people who have the gene expansion for HD, but are currently healthy and have no symptoms. (NCT00051324)

WWW.BOOKBAZ.IR

- The evaluation of the effect of atomoxetine on daily activities such as attention and focus, thinking ability and muscle movements in subjects with early HD. (NCT00368849)
- The collection of prospective data from individuals who are part of HD family to learn more about HD, develop potential treatments for HD, and to plan for future research studies of experimental drugs aimed at slowing or postponing the onset and progression of HD. (NCT00313495)
- The evaluation of the safety of the drug ursodiol in people with HD and the study of how the compound is processed by the body. (NCT00514774)
- The evaluation of the safety and tolerability of dimebon in people with HD. (NCT00387270)
- The effectiveness of a music therapy program to improve holistically the psychological, somatic, and social symptoms of patients with HD. (NCT00178360)
- The assessment of the impact of minocycline on the progression of symptoms of HD. (NCT00277355)

Clinical trial information is constantly updated by NIH and the most recent information on Huntington's disease trials can be found at http://clinicaltrials.gov/search/term=Huntington%27s%20Disease.

Prognosis

The person with HD may be able to maintain a job for several years after diagnosis, despite the increase in disability. Loss of cognitive functions and increase in motor and behavioral symptoms eventually prevent the person with HD from continuing employment. Ultimately, severe motor symptoms prevent mobility. Death usually occurs 15–20 years after disease onset. Progressive weakness of respiratory and swallowing muscles leads to increased risk of respiratory infection and choking, the most common causes of death. Future research in this area is focusing on nerve cell transplantation.

Prevention

Genetic testing is available for HD and should be considered if there is a family history of the disease. The Huntington's Disease Society of America has reputable pre–test and post–test counseling information.

Hydatidiform mole

Definition

A hydatidiform mole is a relatively rare condition in which tissue around a fertilized egg that normally would have developed into the placenta instead develops as an abnormal cluster of cells. (This is also called a molar pregnancy.) This grapelike mass forms inside the uterus after fertilization instead of a normal embryo. A hydatidiform mole triggers a positive **pregnancy** test and in some cases can become cancerous.

Description

A hydatidiform mole ("hydatid" means "drop of water" and "mole" means "spot") occurs in about 1 out of every 1,500 (1:1,500) pregnancies in the United States. In some parts of Asia the incidence may be as high as 1 in 200 (1:200). Molar pregnancies are most likely to occur in younger and older women (especially over age 45) than in those between ages 20–40. About 1–2% of the time a woman who has had a molar pregnancy will have a second one.

A molar pregnancy occurs when cells of the chorionic villi (tiny projections that attach the placenta to the lining of the uterus) do not develop correctly. Instead, they turn into watery clusters that cannot support a growing baby. A partial molar pregnancy includes an abnormal embryo (a fertilized egg that has begun to grow) that does not survive. In a complete molar pregnancy there is a small cluster of clear blisters or pouches that do not contain an embryo.

If not removed, about 15% of **moles** can become cancerous. They burrow into the wall of the uterus and cause serious bleeding. Another 5% will develop into fast-growing cancers called choriocarcinomas. Some of these tumors spread very quickly outside the uterus in other parts of the body. Cancer developing from these moles is rare and highly curable.

Causes and symptoms

The cause of hydatidiform mole is unclear; some experts believe it is caused by problems with the chromosomes (the structures inside cells that contain genetic information) in either the egg or sperm, or both. It may be associated with poor **nutrition** or a problem with the ovaries or the uterus. A mole sometimes can develop from placental tissue that is left behind in the uterus after a **miscarriage** or **childbirth**.

Women with a hydatidiform mole will have a positive pregnancy test and often believe they have a normal pregnancy for the first three or four months. In these cases the uterus will grow abnormally fast. By the end of the third month, if not earlier, the woman will experience vaginal bleeding ranging from scant spotting to excessive bleeding. She may have **hyperthyroidism** (overproduction of **thyroid hormones** causing symptoms such as weight loss, increased appetite, and intolerance to heat). Sometimes, the grapelike cluster of cells itself will be shed with the blood during this time. Other symptoms may include severe **nausea and vomiting** and high blood pressure. As the pregnancy progresses, the fetus will not move and there will be no fetal heartbeat.

Diagnosis

The physician may not suspect a molar pregnancy until after the third month or later, when the absence of a fetal heartbeat together with bleeding and severe nausea and **vomiting** indicates something is amiss.

First, the physician will examine the woman's abdomen, feeling for any strange lumps or abnormalities in

WWW.BOOKBAZ.IR

the uterus. A tubal pregnancy, which can be life threatening if not treated, will be ruled out. Then the physician will check the levels of human chorionic gonadotropin (hCG), a hormone that is normally produced by a placenta or a mole. Abnormally high levels of hCG together with the symptoms of vaginal bleeding, lack of fetal heartbeat, and an unusually large uterus all indicate a molar pregnancy. An **ultrasound** of the uterus to make sure there is no living fetus will confirm the diagnosis.

Treatment

It is extremely important to make sure that all of the mole is removed from the uterus, since it is possible that the tissue is potentially cancerous. Often, the tissue is naturally expelled by the fourth month of pregnancy. In some instances, the physician will give the woman a drug called oxytocin to trigger the release of the mole that is not spontaneously aborted.

If this does not happen a vacuum aspiration can be performed to remove the mole. In a procedure similar to a **dilatation and curettage** (D & C), a woman is given an anesthetic (to deaden feeling during the procedure), her cervix (the structure at the bottom of the uterus) is dilated and the contents of the uterus is gently suctioned out. After the mole has been mostly removed, gentle scraping of the uterus lining is usually performed.

If the woman is older and does not want any more children, the uterus can be surgically removed (**hysterectomy**) instead of a vacuum aspiration because of the higher risk of cancerous moles in this age group.

Because of the cancer risk, the physician will continue to monitor the patient for at least two months after the end of a molar pregnancy. Since invasive disease is usually signaled by high levels of hCG that do not go down after the pregnancy has ended, the woman's hCG levels will be checked every two weeks. If the levels do not return to normal by that time, the mole may have become cancerous.

If the hCG level is normal, the woman's hCG will be tested each month for six months, and then every two months for a year.

If the mole has become cancerous, treatment includes removal of the cancerous issue and **chemotherapy**. If the cancer has spread to other parts of the body, radiation will be added. Specific treatment depends on how advanced the cancer is.

Women should make sure not to become pregnant within a year after hCG levels have returned to normal. If a woman were to become pregnant sooner than that, it would be difficult to tell whether the resulting high levels of hCG were caused by the pregnancy or a cancer from the mole.

Prognosis

A woman with a molar pregnancy often goes through the same emotions and sense of loss as does a woman who has a miscarriage. Most of the time, she truly believed she was pregnant and now has suffered a loss of the baby she thought she was carrying. In addition, there is the added worry that the tissue left behind could become cancerous.

In the unlikely case that the mole is cancerous the cure rate is almost 100%. As long as the uterus was not removed, it would still be possible to have a child at a later time.

Hydrocelectomy

Definition

Hydrocelectomy, also called hydrocele repair, is the surgical removal of a hydrocele. A hydrocele is a fluid-filled sac along the spermatic cord within a testicle. It forms from a backup of peritoneal (abdominal) fluid in a membrane called the tunica vaginalis, which covers the front and sides of the male testes.

Purpose

A hydrocelectomy is performed to remove a hydrocele and prevent its recurrence. In babies a hydrocelectomy is used to remove a congenital (present at birth) hydrocele that has not resolved on its own by the age of two. In adults hydrocelectomies are used to repair hydroceles that:

- are large, painful, or embarrassing
- cause swelling of the scrotum
- reoccur following aspiration of the hydrocele
- interfere with the blood supply in the testicle
- are associated with an inguinal hernia

Demographics

Hydroceles occur in at least 80% of male infants, but almost always disappear on their own by the age of two. They also can occur in older boys and men. About 1% of adult males over age 40 develop hydroceles.

Description

During development of the male fetus the testicles descend down a tube from the abdomen into the scrotum. Congenital hydroceles are most often caused by a failure of a portion of the testicular membrane—the processus vaginalis that descends with the testicles—to close normally. This failure to close allows peritoneal fluid to flow into the scrotum and becomes trapped. However, the processus vaginalis usually closes spontaneously within the first year of life and the hydrocele disappears. The processus does not usually close spontaneously after the age of 18 months.

In adults hydroceles develop slowly and increase and decrease in size over time. They are usually a result either of a defect in the tunica vaginalis that causes overproduction of fluid or a blocked lymphatic flow that may be related to an obstruction in the spermatic cord. The latter type of hydrocele is more common in older men. Hydroceles can also develop from inflammation, injury, or infection of the epididymis or testicle, **trauma** to the scrotal area, or in association with an inguinal **hernia** or cancerous tumors in the groin.

Hydroceles usually appear as a soft swelling in the membrane surrounding the testes. Hydroceles typically occur in one testis—only 7–10% occur on both sides of the scrotum. They are not usually painful and do not damage the testes; however, as the hydrocele fills with fluid some men may experience discomfort or **pain** from the increased size of the scrotum. If a hydrocele occurs in conjunction with **epididymitis** (inflammation of the epididymis), the testis may become painful and inflamed.

Hydroceles can sometimes be diagnosed in a doctor's office by visual examination and palpation (touch). Hydroceles are distinguished from other testicular problems by transillumination (shining a light source through the hydrocele so that the tissue lights up) and **ultrasound** examinations of the area around the groin and scrotum.

Although the fluid from a hydrocele can be removed through a needle by aspiration, this is usually a temporary measure because the hydrocele often recurs. Aspiration may have longer-term success when certain medications are injected during the procedure (sclerotherapy). There is a higher risk of infection with aspiration than with hydrocelectomy.

A hydrocelectomy is performed by a general surgeon or a urologist on an outpatient basis in a clinic, one-day surgery center, or hospital operating room, with no special precautions. Patients are given general **anesthesia**. The extent of the surgery depends on the presence of other problems:

- For a hydrocelectomy in a child, a small incision is made in the fold of the groin, the fluid is drained, and the hydrocele sac is removed. The muscle wall is then strengthened with stitches.
- For an uncomplicated hydrocele in an adult, an incision is made directly into the scrotum. The canal between the abdominal cavity and the scrotum is repaired, the hydrocele sac is removed, the fluid is drained from the scrotum, and the incision is closed with sutures.
- For more complicated hydrocelectomies, such as those associated with an inguinal hernia, the incision is made in the groin area and the hernia or other complicating factor is repaired along with hydrocele removal.
- Sometimes a hydrocelectomy is performed by minimally invasive laparoscopic surgery. A lighted, camera-tipped, tube-like instrument called a laparoscope is inserted through a tiny incision. Instruments can be passed through the laparoscope or inserted through other small incisions. The repair is completed by visualizing images on a monitor in the operating room.

Results

Hydrocelectomy usually eliminates the hydrocele and completely corrects any underlying defect. Recurrence of hydroceles are rare and the long-term prognosis is excellent.

Precautions

Children can resume normal activities in four to seven days following a hydrocelectomy. Adults can resume most activities within 7 to 10 days, although heavy lifting and sexual activities may be delayed for up to six weeks. There may be swelling of the scrotum for a month or more after the procedure; however, prolonged swelling, **fever**, or redness in the incision area should be reported to the surgeon immediately. There have been no reports of death following a hydrocele repair.

WWW.BOOKBAZ.IR

KEY TERMS

Aspiration—The process of removing fluids or gases from the body by suction.

Epididymis—A coiled segment of spermatic duct within the scrotum, attached to the back of the testis.

Epididymitis—Inflammation of the epididymis.

Hydrocele—An accumulation of fluid in the membrane that surrounds the testis.

Inguinal hernia—An opening, weakness, or bulge in the lining of the abdominal wall in the groin area, with protrusion of the large intestine.

Peritoneal fluid—Fluid from the abdominal cavity.

Processus vaginalis—A pouch of the peritoneum (lining of the abdominal cavity) that is carried into the scrotum with the descent of the testicles to become the tunica vaginalis.

Scrotum—The pouch of skin containing the testes, epididymis, and portions of the spermatic cords.

Testis (plural: testes)—The male sex gland, held within the scrotum.

Transillumination—A technique by which a strong light is shone through body tissues to examine an organ or structure.

Tunica vaginalis—A sac-like membrane covering the outer surface of the testis.

Preparation

Prior to the hydrocelectomy standard preoperative blood and urine tests will be performed. Several days before the surgery adults may be asked to stop taking any drugs that affect blood clotting. These include **aspirin**, ibuprofen (Motrin, Advil), naproxen (Naprosyn, Aleve), and some herbal supplements. The patient may be asked to not eat or drink for at least six hours before the surgery. An anesthesiologist will discuss the patient's medical history to select the correct type and amount of anesthesia. The physician or nurse will explain the surgical procedure, the type of anesthesia, and, in some cases, the need to insert a temporary drain during surgery to reduce the risk of postoperative infection and fluid accumulation.

Aftercare

Immediately following the hydrocelectomy the patient will be moved to a recovery area and checked for any undue bleeding from the incision. Body temperature and blood pressure will be monitored. Patients usually return home within a few hours. A follow-up visit is usually required several weeks after the surgery to examine the incision for proper healing and any signs of infection.

Risks

Hydrocelectomy is considered a very safe surgery, with only a 2% risk of infection or complications. It is possible for a hydrocelectomy to cause injury to spermatic vessels that can affect fertility. Most surgical procedures carry some risk of problems related to anesthesia, including allergic reactions or breathing difficulties. Most surgeries also carry some risk of bleeding from the incision, internal bleeding, **blood clots**, or infection.

REVISED BY MARGARET ALIC, PhD

Hydrocephalus

Definition

Hydrocephalus is an abnormal expansion of cavities (ventricles) within the brain that is caused by the accumulation of cerebrospinal fluid. Hydrocephalus comes from two Greek words: *hydros* means water and *cephalus* means head.

There are two main varieties of hydrocephalus: congenital and acquired. An obstruction of the cerebral aqueduct (aqueductal stenosis) is the most frequent cause of congenital hydrocephalus. Acquired hydrocephalus may result from **spina bifida**, intraventricular hemorrhage, **meningitis**, head **trauma**, tumors, and cysts.

Description

Hydrocephalus is the result of an imbalance between the formation and drainage of cerebrospinal fluid (CSF). Approximately 500 mL (about a pint) of CSF is formed within the brain each day, by epidermal cells in structures collectively called the choroid plexus. These cells line chambers called ventricles that are located within the brain. There are four ventricles in a human brain. Once formed, CSF usually circulates among all the ventricles before it is absorbed and returned to the circulatory system. The normal adult volume of circulating CSF is 150 mL. The CSF turn-over rate is more than three times per day. Because production is independent of absorption, reduced absorption causes CSF to accumulate within the ventricles.

There are three different types of hydrocephalus. In the most common variety, reduced absorption occurs when one or more passages connecting the ventricles become blocked. This prevents the movement of CSF to its drainage sites in the subarachnoid space just inside the skull. This type of hydrocephalus is called noncommunicating. In a second type, a reduction in the absorption rate is caused by damage to the absorptive tissue. This variety is called communicating hydrocephalus.

Both of these types lead to an elevation of the CSF pressure within the brain. This increased pressure pushes aside the soft tissues of the brain. This squeezes and distorts them. This process also results in damage to these tissues. In infants whose skull bones have not yet fused, the intracranial pressure is partly relieved by expansion of the skull, so that symptoms may not be as dramatic. Both types of elevated-pressure hydrocephalus may occur from infancy to adulthood.

A third type of hydrocephalus, called normal pressure hydrocephalus, is marked by ventricle enlargement without an apparent increase in CSF pressure. This type affects mainly the elderly.

Hydrocephalus has a variety of causes including:

- congenital brain defects
- hemorrhage, either into the ventricles or the subarachnoid space
- infection of the central nervous system (syphilis, herpes, meningitis, encephalitis, or mumps)
- tumor

Hydrocephalus is believed to occur in approximately one to two of every 1,000 live births. The incidence of adult onset hydrocephalus is not known. There is no known way to prevent hydrocephalus.

Causes and symptoms

Hydrocephalus that is congenital (present at birth) is thought to be caused by a complex interaction of genetic and environmental factors. Aqueductal stenosis, an obstruction of the cerebral aqueduct, is the most frequent cause of congenital hydrocephalus. The genetic factors are not well understood. According to the British Association for Spina Bifida and Hydrocephalus, in very rare circumstances, hydrocephalus is due to hereditary factors, which might affect future generations.

Signs and symptoms of elevated-pressure hydrocephalus include:

- headache
- nausea and vomiting, especially in the morning
- lethargy
- disturbances in walking (gait)
- double vision
- subtle difficulties in learning and memory
- delay in children achieving developmental milestones

Irritability is the most common sign of hydrocephalus in infants. If this is not treated, it may lead to lethargy. Bulging of the fontanelles, or the soft spots between the skull bones, may also be an early sign. When hydrocephalus occurs in infants, fusion of the skull bones is prevented. This leads to abnormal expansion of the skull.

Symptoms of normal pressure hydrocephalus include **dementia**, gait abnormalities, and incontinence (involuntary urination or bowel movements).

Diagnosis

Imaging studies—x ray, computed tomography scan (CT scan), **ultrasound**, and especially **magnetic resonance imaging** (MRI)—are used to assess the presence and location of obstructions, as well as changes in brain tissue that have occurred as a result of the hydrocephalus. **Lumbar puncture** (spinal tap) may be performed to aid in determining the cause when infection is suspected.

WWW.BOOKBAZ.IR

Treatment

The primary method of treatment for both elevated and normal pressure hydrocephalus is surgical installation of a shunt. A shunt is a tube connecting the ventricles of the brain to an alternative drainage site, usually the abdominal cavity. A shunt contains a one-way valve to prevent reverse flow of fluid. In some cases of non-communicating hydrocephalus, a direct connection can be made between one of the ventricles and the subarachnoid space, allowing drainage without a shunt.

Installation of a shunt requires lifelong monitoring by the recipient or family members for signs of recurring hydrocephalus due to obstruction or failure of the shunt. Other than monitoring, no other management activity is usually required.

Some drugs may postpone the need for surgery by inhibiting the production of CSF. These include acetazolamide and furosemide. Other drugs that are used to delay surgery include glycerol, **digoxin**, and isosorbide.

Some cases of elevated pressure hydrocephalus may be avoided by preventing or treating the infectious diseases that precede them. Prenatal diagnosis of congenital brain malformation is often possible, offering the option of family planning.

Prognosis

The prognosis for elevated-pressure hydrocephalus depends on a wide variety of factors, including the cause, age of onset, and the timing of surgery. Studies indicate that about half of all children who receive appropriate treatment and follow-up will develop IQs greater than 85. Those with hydrocephalus at birth do better than those with later onset due to meningitis. For individuals with normal pressure hydrocephalus, approximately half will benefit by the installation of a shunt.

Hydronephrosis

Definition

Hydronephrosis is the swelling of the kidneys when urine flow is obstructed in any of part of the urinary tract. Swelling of the ureter, which always accompanies hydronephrosis, is called hydroureter. Hydronephrosis implies that a ureter and the renal pelvis (the connection of the ureter to the kidney) are overfilled with urine.

Description

The kidneys filter urine out of the blood as a waste product. It collects in the renal pelvis and flows down the ureters into the bladder. The ureters are not simple tubes, but muscular passages that actively propel urine into the bladder. At their lower end is a valve (the ureterovesical junction) that prevents urine from flowing backward into the ureter. The bladder stores urine. The prostate gland surrounds the bladder outlet in males. Urine then flows through the urethra and out of the body as a waste product.

Because the urinary tract is closed save for the one opening at the bottom, urine cannot escape. Instead, the parts distend. Rupture is rare unless there is violent **trauma** like an automobile accident.

Obstructed flow anywhere along the drainage route can cause swelling of the upper urinary tract, but if the obstruction is below the bladder, the ureterovesical valve will protect the upper tract to a certain extent. Even then, with no place to go, the urine will back up all the way to its source. Eventually, the back pressure causes kidney function to deteriorate.

Obstruction need not be complete for problems to arise. Intermittent or partial obstruction is far more

common than complete blockage, allowing time for the parts to enlarge gradually. Furthermore, if a ureterovesical valve is absent or incompetent, the pressure generated by bladder emptying will force urine backward into the ureter and kidney, causing dilation even without mechanical obstruction.

Causes and symptoms

There are numerous causes for hydronephrosis. Various congenital deformities of the ureter may sooner or later produce back pressure. **Kidney stones** are a common cause. They form in the renal pelvis and become lodged in the kidney, usually at the ureterovesical junction. In older men, the continued growth of the prostate gland leads commonly to restricted urine flow out of the bladder. **Prostate cancer**, and cancer anywhere else along the urine pathways, can obstruct flow. **Pregnancy** normally causes ureteral obstruction from the pressure of the enlarged uterus (womb) on the ureters.

Symptoms relate to the passage of urine. Sometimes, urine may be difficult to pass, irregular, or uncontrolled. **Pain** from distension of the structures is present. Blood in the urine may be visible, but it is usually microscopic.

In all cases where bodily fluids cannot flow freely, infection is inevitable. Symptoms of urinary infection may include:

- painful, burning urine
- cloudy urine
- pain in the back, flank, or groin
- fever, sweats, chills, and generalized discomfort

Patients often mistake a serious urinary infection for the flu.

Diagnosis

If the bladder is significantly distended, it can be felt through the abdomen. An analysis of the urine may reveal blood (if there is a stone), infection, or chemical changes suggesting kidney damage. Blood tests may also detect a decrease in kidney function.

All urinary obstructions will undergo imaging of some sort. Beginning with standard x rays to look for stones, radiologists, physicians specializing in the use of radiant energy for diagnostic purposes, will select from a wide array of tests. **Ultrasound** is simple, inexpensive, and very useful for these conditions. Standard x rays can be enhanced with contrast agents in several ways. If the kidneys are functioning, they will filter an x ray dye out of the blood and concentrate it in the urine, giving excellent pictures and also an assessment of kidney function. For better images of the lower urinary tract, contrast agents can be instilled from below. This is usually done with a cystoscope placed in the bladder. Through the cystoscope, a small tube can be threaded into the ureter through the ureterovesical valve, allowing dye to be injected all the way up to the kidney. CT and MRI scanning provide miraculous detail, more than is often needed for this condition.

Treatment

The obstruction must be relieved, even if it is partial or functional, as in the case of reflux from the bladder. If not, the kidney will ultimately be damaged, infection will appear, or both. The task may be as simple as placing a catheter through a restricting prostate or as complicated as removing a cancerous bladder and rebuilding a new one with a piece of bowel. In some cases, a badly damaged kidney may have to be removed.

Alternatives

Catheters or other urinary diversions may be better for weak or ill patients who cannot tolerate more extensive procedures. There is support using botanical medicine that can help the patient using a catheter avoid infections. Consultation with a trained health care practitioner is necessary.

Prognosis

After relief of the obstruction, a kidney may react with a brief flood of urine, but if the obstruction has been of short duration, normal kidney function will return. If one kidney is destroyed, the other will compensate for the lost organ.

Prevention

Kidney stones can be prevented by dietary changes and medication. Prompt evaluation of infections and urinary complaints will usually detect problems early enough to prevent long-term complications.

Hydrotherapy

Definition

Hydrotherapy, or water therapy, is the use of water (hot, cold, steam, or ice) to relieve discomfort and promote physical well-being.

Purpose

Hydrotherapy can soothe sore or inflamed muscles and joints, rehabilitate injured limbs, lower fevers, soothe headaches, promote relaxation, treat **burns** and frostbite, ease labor pains, and clear up skin problems. The temperature of water used affects the therapeutic properties of the treatment. Hot water is chosen for its relaxing properties. It is also thought to stimulate the immune system. Tepid water can also be used for **stress reduction**, and may be particularly relaxing in hot weather. Cold water is selected to reduce inflammation. Alternating hot and cold water can stimulate the circulatory system and improve the immune system. Adding herbs and essential oils to water can enhance its therapeutic value. Steam is frequently used as a carrier for essential oils that are inhaled to treat respiratory problems.

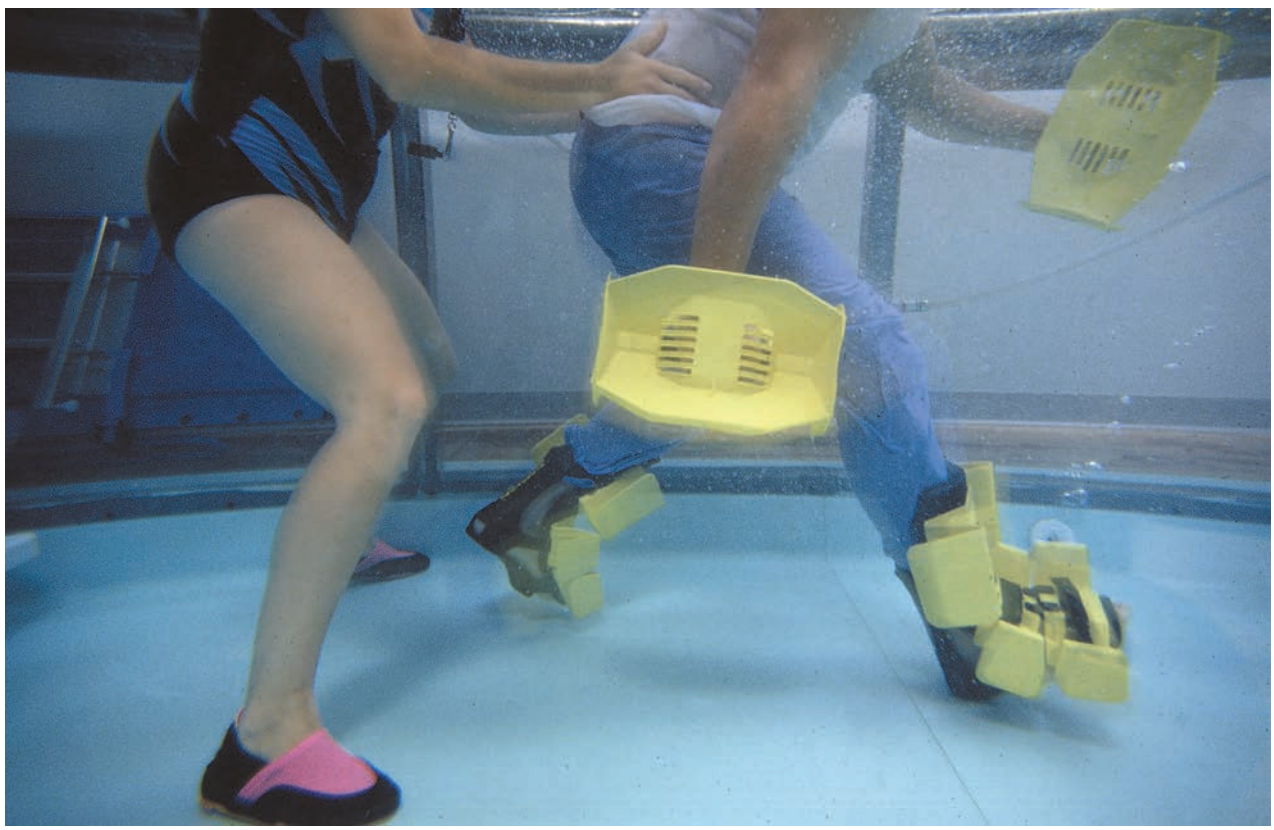
Since the late 1990s, hydrotherapy has been used in critical care units to treat a variety of serious conditions, including such disorders of the nervous system as Guillain-Barré syndrome.

Description

Origins

The therapeutic use of water has a long history. Ruins of an ancient bath were unearthed in Pakistan and date as far back as 4500 B.C. Bathhouses were an essential part of ancient Roman culture. The use of steam, baths, and aromatic massage to promote well being is documented since the first century. Roman physicians Galen and Celsus wrote of treating patients with warm and cold baths in order to prevent disease.

By the seventeenth and eighteenth centuries, bathhouses were extremely popular with the public throughout Europe. Public bathhouses made their first American appearance in the mid 1700s.



A patient (holding paddles) is undergoing a hydrotherapy treatment. *(Will & Deni McIntyre/Photo Researchers, Inc.)*

In the early nineteenth century, Sebastien Kneipp, a Bavarian priest and proponent of water healing, began treating his parishioners with cold water applications after he himself was cured of **tuberculosis** through the same methods. Kneipp wrote extensively on the subject, and opened a series of hydrotherapy clinics known as the Kneipp clinics, which are still in operation today. Around the same time in Austria, Vincenz Priessnitz was treating patients with baths, packs, and showers of cold spring water. Priessnitz also opened a spa that treated over 1,500 patients in its first year of operation, and became a model for physicians and other specialists to learn the techniques of hydrotherapy.

Water can be used therapeutically in a number of ways. Common forms of hydrotherapy include:

- Whirlpools, jacuzzis, and hot tubs. These soaking tubs use jet streams to massage the body. They are frequently used by physical therapists to help injured patients regain muscle strength and to soothe joint and muscle pain. Some midwives and obstetricians also approve of the use of hot tubs to soothe the pain of labor.
- Pools and Hubbard tanks. Physical therapists and rehabilitation specialists may prescribe underwater pool exercises as a low-impact method of rebuilding muscle strength in injured patients. The buoyancy experienced during pool immersion also helps ease pain in conditions such as arthritis.
- Baths. Tepid baths are prescribed to reduce a fever. Baths are also one of the oldest forms of relaxation therapy. Aromatherapists often recommend adding essential oils of lavender (*Lavandula angustifolia*) to a warm to hot bath to promote relaxation and stress reduction. Adding Epsom salts (magnesium sulfate) or Dead Sea salts to a bath can also promote relaxation and soothe rheumatism and arthritis.
- Showers. Showers are often prescribed to stimulate the circulation. Water jets from a shower head are also used to massage sore muscles. In addition, showering hydrotherapy has been shown to be preferable to immersion hydrotherapy for treating burn patients.
- Moist compresses. Cold, moist compresses can reduce swelling and inflammation of an injury. They can also be used to cool a fever and treat a headache. Hot or warm compresses are useful for soothing muscle aches and treating abscesses.
- Steam treatments and saunas. Steam rooms and saunas are recommended to open the skin pores and cleanse the body of toxins. Steam inhalation is prescribed to treat respiratory infections. Adding botanicals to the steam bath can increase its therapeutic value.
- Internal hydrotherapy. Colonic irrigation is an enema that is designed to cleanse the entire bowel. Proponents of the therapy say it can cure a number of digestive problems. Douching, another form of internal hydrotherapy, directs a stream of water into the vagina for cleansing purposes. The water may or may not contain medications or other substances. Douches can be self-administered with kits available at most drug stores.

Preparations

Because of the expense of the equipment and the expertise required to administer effective treatment, hydrotherapy with pools, whirlpools, Hubbard tanks, and saunas is best taken in a professional healthcare facility, and/or under the supervision of a healthcare professional. Baths, steam inhalation treatments, and compresses can be easily administered at home.

Bath preparations

Warm to hot bath water should be used for relaxation purposes, and a tepid bath is recommended for reducing fevers. Herbs can greatly enhance the therapeutic value of the bath for a variety of illnesses and minor discomforts.

Herbs for the bath can be added to the bath in two ways—as essential oils or whole herbs and flowers. Whole herbs and flowers can be placed in a muslin or cheesecloth bag that is tied at the top to make an herbal bath bag. The herbal bath bag is then soaked in the warm tub, and can remain there throughout the bath. When using essential oils, add 5–10 drops of oil to a full tub. Oils can be combined to enhance their therapeutic value. Marjoram (*Origanum marjorana*) is good for relieving sore muscles; juniper (*Juniperus communis*) is recommended as a detoxifying agent for the treatment of arthritis; lavender, ylang ylang (*Conanga odorata*), and chamomile (*Chamaemelum nobilis*) are recommended for **stress** relief; cypress (*Cupressus sempervirens*), yarrow (*Achillea millefolium*), geranium (*Pelargonium graveolens*), clary sage (*Savlia sclaria*), and myrtle (*Myrtus communis*) can promote healing of **hemorrhoids**; and spike lavender and juniper (*Juniperus communis*) are recommended for rheumatism.

To prepare salts for the bath, add one or two handfuls of epsom salts or Dead Sea salts to boiling water until they are dissolved, and then add them to the tub.

A **sitz bath**, or hip bath, can also be taken at home to treat hemorrhoids and promote healing of an

VINZENZ PRIESSNITZ (1799–1851)

Vincenz Priessnitz *(Corbis.)*

Hydrotherapy inventor Vinzenz Priessnitz was the son of a Silesian farmer from a remote Austrian territory in the Jeseniky Mountains. From the age of 12, Priessnitz dutifully provided for his blind father, his elderly mother, and his sister. His formal education was sporadic at best. However, Priessnitz possessed a level head and a high degree of intelligence along with a keen and active mind. As he matured he became extremely aware of his surroundings in nature.

At age 16, Priessnitz fell from a horse and was seriously hoofed by the animal. He received the morbid prognosis that he might be crippled at best, or might die at worst. He set to treating his own chest wound with cold packs, in emulation of a doe that he had once observed bathing a wound in a cool mountain stream. The hydrotherapy regimen proved highly effective and drew considerable attention to his small hometown of Gräfenberg. In 1822 he rebuilt the family home, renovating its wooden frame into a solid brick spa structure. The spa, known as the castle, housed as many as 1,500 guests each year by 1939. Among the guests were medical professionals who were intent upon exposing the therapy as a sham.

Detractors notwithstanding, word of the simple and effective treatment spread to Vienna, where Priessnitz traveled on occasion to provide counsel at the emperor's court. Priessnitz, for his remarkable discovery, received the Austrian Gold Civil Merit Medal First Class, the highest civilian honor of the Austrian government.

Priessnitz died on November 28, 1851. He was survived by a wife, Zofie Priessnitz, and a young son, Vinzenz Pavel. Joseph Schindler took over the operation of the spa at Gräfenberg following the death of its founder.

episiotomy. There is special apparatus available for taking a seated sitz bath, but it can also be taken in a regular tub partially filled with warm water.

Steam inhalation

Steam inhalation treatments can be easily administered with a bowl of steaming water and a large towel. For colds and other conditions with nasal congestion, aromatherapists recommend adding five drops of an essential oil that has decongestant properties, such as peppermint (*Mentha piperita*) and eucalyptus blue gum (*Eucalyptus globulus*). Oils that act as **expectorants**, such as myrtle (*Myrtus communis*) or rosemary (*Rosmarinus officinalis*), can also be used. After the oil is added, the individual should lean over the bowl of water and place the towel over head to trap the steam. After approximately three minutes of inhaling the steam, with eyes closed, the towel can be removed.

Other herbs and essential oils that can be beneficial in steam inhalation include:

- tea tree oil (*Melaleuca alternaifolia*) for bronchitis and sinus infections
- sandalwood (*Santalum album*), virginian cedarwood (*Juniperus virginiana*), and frankincense (*Boswellia carteri*) for sore throat
- lavender (*Lavandula angustifolia*) and thyme (*Thymus vulgaris*) for cough

Compresses

A cold compress is prepared by soaking a cloth or cotton pad in cold water and then applying it to the area of injury or distress. When the cloth reaches room temperature, it should be resoaked and reapplied. Applying gentle pressure to the compress with the hand may be useful. Cold compresses are generally used to reduce swelling, minimize bruising, and to treat headaches and sprains.

Warm or hot compresses are used to treat abscesses and muscle aches. A warm compress is prepared in the same manner as a cold compress, except steaming water is used to wet the cloth instead of cold water. Warm

compresses should be refreshed and reapplied after they cool to room temperature.

Essential oils may be added to moist compresses to increase the therapeutic value of the treatment. Peppermint, a cooling oil, is especially effective when added to cold compresses. To add oils to compresses, place five drops of the oil into the bowl of water the compress is to be soaked in. Never apply essential oils directly to a cloth, as they may irritate the skin in undiluted form.

Precautions

Individuals with **paralysis**, frostbite, or other conditions that impair the nerve endings and cause reduced sensation should only take hydrotherapy treatments under the guidance of a trained hydrotherapist, physical therapist, or other appropriate healthcare professional. Because these individuals cannot accurately sense temperature changes in the water, they run the risk of being seriously burned without proper supervision. Diabetics and people with **hypertension** should also consult their healthcare professional before using hot tubs or other heat hydrotherapies.

Hot tubs, jacuzzis, and pools can become breeding grounds for bacteria and other infectious organisms if they are not cleaned regularly, maintained properly, kept at the appropriate temperatures, and treated with the proper chemicals. Individuals should check with their healthcare provider to ensure that the hydrotherapy equipment they are using is sanitary. Those who are using hot tubs and other hydrotherapy equipment in their homes should follow the directions for use and maintenance provided by the original equipment manufacturer.

Certain essential oils should not be used by pregnant or nursing women or by people with specific illnesses or physical conditions. Individuals with any chronic or acute health condition should inform their healthcare provider before starting treatment with any essential oil.

Essential oils such as cinnamon leaf, juniper, lemon, eucalyptus blue gum, peppermint, and thyme can be extremely irritating to the skin if applied in full concentration. Oils used in hydrotherapy should always be diluted in water before they are applied to the skin. Individuals should never apply essential oils directly to the skin unless directed to do so by a trained healthcare professional and/or aromatherapist.

Colonic irrigation should only be performed by a healthcare professional. Pregnant women should never douche, as the practice can introduce bacteria into the vagina and uterus. They should also avoid using hot tubs without the consent of their healthcare provider.

The vagina is self-cleansing, and douches have been known to upset the balance of vaginal pH and flora, promoting **vaginitis** and other infections. Some studies have linked excessive vaginal douching to increased incidence of **pelvic inflammatory disease** (PID).

Side effects

Most forms of hydrotherapy are well tolerated. There is a risk of allergic reaction (also known as **contact dermatitis**) for some patients using essential oils and herbs in their bath water. These individuals may want to test for allergic sensitization to herbs by performing a skin patch test (i.e., rubbing a small amount of diluted herb on the inside of their elbow and observing the spot for redness and irritation). People who experience an allergic reaction to an essential oil should discontinue its use and contact their healthcare professional for further guidance.

The most serious possible side effect of hydrotherapy is overheating, which may occur when an individual spends too much time in a hot tub or jacuzzi. However, when properly supervised, this is a minimal risk.

Research and general acceptance

Hydrotherapy treatments are used by both allopathic and complementary medicine to treat a wide variety of discomforts and disorders. Not as well accepted are invasive hydrotherapy techniques, such as colonic irrigation, **enemas**, and douching. These internal cleansing techniques can actually harm an individual by upsetting the natural balance of the digestive tract and the vagina. Most conventional medical professionals agree that vaginal douches are not necessary to promote hygiene in most women, and can actually do more harm than good.

Hyperaldosteronism

Definition

Hyperaldosteronism is a disorder that is defined by the body's overproduction of aldosterone, a hormone that controls **sodium** and potassium levels in the blood. Its overproduction leads to retention of salt and loss of potassium, which leads to **hypertension** (high blood pressure).

Description

Also known as Conn's syndrome, primary aldosteronism, and secondary aldosteronism, this disorder takes several forms. It often begins with a tumor that produces aldosterone. Approximately 60–70% of the cases of primary aldosteronism result from tumors in the adrenal gland area. Aldosterone is normally produced by the adrenal cortex, or the outer portion of the gland that rests on top of each kidney. Primary aldosteronism is due to adenoma, a typically benign tumor in which the cells form to act as glands or cause the glands on which they rest to overproduce. It can cause a number of problems, most notably hypertension. In secondary aldosteronism, factors outside the adrenal gland may cause overproduction of aldosterone, or overproduction of renin, an enzyme stored in the kidney area that stimulates aldosterone and raises blood pressure. Obstructive renal artery disease may also cause hypertension from elevated renin stimulating aldosterone. **Oral contraceptives** have been known to increase the secretion of aldosterone in some patients. This disorder is more common in women.

Causes and symptoms

Hyperaldosteronism is most often caused by the invasion of adenoma. Other adrenal cancers and hyperplasia, or the increase in the bulk of an organ due to increased cell production, may also cause hyperaldosteronism. Those diseases and factors influencing the adrenal and kidney functions may lead to secondary aldosteronism. The primary symptom of hyperaldosteronism is moderate hypertension, or high blood pressure. In addition, a patient may experience **orthostatic hypotension**, or reduced blood pressure when a person stands after lying down. **Constipation**, muscle weakness (sometimes to the point of **periodic paralysis**), excessive urination, excessive thirst, **headache**, and personality changes are also possible symptoms. Some patients will show no obvious symptoms.

Diagnosis

Screening tests can be conducted to pinpoint a diagnosis of hyperaldosteronism. If a patient is taking drugs to reduce high blood pressure, the physician may order these drugs stopped for a time period before conducting tests, since these drugs will affect results. Blood and urine tests may be conducted to check for levels of aldosterone, potassium levels, or renin activity. A computed tomography scan (CT scan) may be ordered to detect tumors as small as 5–7 mm. These combined tests approach 95% accuracy for detecting aldosterone-producing adenoma. Laboratory findings recording blood pressure, **edema**, and aldosterone and **plasma renin activity** can help the physician differentiate between primary aldosteronism and secondary aldosteronism.

Treatment

Once the physician has made a diagnosis of hyperaldosteronism, the adrenal glands should be checked for possible adenomas. This can be done through imaging or with a surgical dissection of the gland. Surgical or ablative treatment will vary depending on the number of tumors found. Since more than 60% of hyperaldosteronism cases are caused by these tumors, treatment of the tumors will help eliminate the resulting high blood pressure in many patients. Some patients will receive **antihypertensive drugs**, like **calcium channel blockers**, to control high blood pressure. The use of **diuretics** can help control hypertension by reducing volume. Potassium levels should be considered in the type of diuretic ordered and the levels should be checked throughout treatment. The most widely used drug for treatment of hyperaldosteronism is spironolactone. This drug helps control aldosterone, but should not be prescribed for some patients, especially those with certain kidney diseases. Spironolactone has several possible adverse effects, depending on the dosage. In all cases of hyperaldosteronism, the treatment should be carefully based on the specific type or underlying cause of the disorder.

Alternatives

Patients may choose to work with their physician or alternative provider to control hypertension with diet, **stress reduction** (including massage, **meditation**, **biofeedback**, and **yoga**), and other remedies. Blood pressure elevation needs to be controlled and monitored by frequent blood pressure measurements. There is no alternative treatment known for the underlying adenoma.

Prognosis

Hyperaldosteronism carries with it all the possible complications of high blood pressure, including thickening of arterial walls and a higher risk of **angina**, kidney failure, **stroke**, or **heart attack**. Another possible, and less reversible complication than hypertension, is kidney damage. When primary aldosteronism is caused by a solitary adenoma, the prognosis is good. Once this tumor is removed, blood pressure will drop, and 70% of these patients have full remission. Patients whose hyperaldosteronism results from adrenal hyperplasia will remain hypertensive. However, in up to 70% of patients, blood pressure can be reduced somewhat with drug therapy. Many patients will be faced with the prospect of controlling their hypertension for the remainder of their lives.

Prevention

There is no known prevention for most causes of hyperaldosteronism.

Hyperbaric chamber *see* **Hyperbaric oxygen therapy**

Hyperbaric oxygen therapy

Definition

Hyperbaric **oxygen therapy** is a treatment that involves placing an individual in a special chamber that supplies them with 100% pure oxygen at a greater than normal atmosphere of pressure.

Purpose

Hyperbaric chambers are used to deliver hyperbaric oxygen therapy (HBOT). HBOT was developed to treat underwater divers who had **decompression sickness** (the bends). It has since been approved by the Undersea and Hyperbaric Medical Society for 14 conditions including:

- Air or gas embolism
- Carbon monoxide (CO) poisoning, with or without cyanide poisoning as a complication
- Gas gangrene due to clostridium bacteria
- Crush injuries, compartment syndrome, and other injuries complicated by lack of oxygen to the tissues
- Decompression sickness
- Wounds or conditions due to arterial insufficiency (including blockage of the retinal artery in the eye)

WWW.BOOKBAZ.IR

Patient lying in a hyperbaric chamber. *(© Chuck Mason/ Alamy.)*

- Severe anemia
- Brain abscesses
- Destructive (necrotizing) soft tissue infections
- Bone infections (osteomyelitis) that fail to heal with conventional treatment
- Tissue injury after radiation treatment
- Grafts and skin flaps that are not healing well
- Thermal injuries and burns
- Idiopathic sudden sensorineural hearing loss (sudden onset deafness due to nerve damage)

Although hyperbaric therapy has become increasingly popular for other uses, especially in sports medicine, its use is controversial. Terrell Owens of the Philadelphia Eagles used HBOT for an ankle injury prior to playing in the Super Bowl in 2005, but medical professionals questioned the appropriateness of this treatment.

Precautions

Individuals who have lung disease, including **asthma**, **emphysema**, obstructive lung disease, or any condition in which air is trapped in the lungs, are poor candidates for this therapy and should discuss the relative benefits and drawbacks of HBOT with their doctor. Individuals who have had chest surgery or who have had a central venous catheter implanted are also at higher risk for complications. People with seizure disorders should be carefully monitored, as this treatment may increase the risk and severity of seizures. People with colds or clogged ears may want to wait to undergo HBOT, as they may experience difficulties with pressure equalization that can cause damage to the middle or inner ear. HBOT in **pregnancy** is controversial. Individuals with diabetes may need to adjust their glucose and insulin balance, since HBOT slows the absorption of insulin.

Description

At normal atmospheric pressure, oxygen binds with a molecule in red blood cells called hemoglobin. The oxygen is carried through the body to tissues where it is needed as the blood circulates. Under normal conditions, almost all (about 97%) of the available hemoglobin carries oxygen. Increasing the atmospheric pressure does little to increase the oxygen-carrying capacity of the blood. However, under normal conditions, only a small amount of oxygen is dissolved in the fluid that carries the red blood cells (blood plasma). Increasing the atmospheric pressure to two to three times normal and breathing 100% oxygen forces more oxygen to dissolve into the blood plasma. In this way, hyperbaric chambers increase the amount of oxygen circulating in the body. This can promote healing in areas that are not receiving adequate oxygen. The extra oxygen can also help to cure certain infections caused by anerobic bacteria that can live only in the absence of oxygen.

There are two types of hyperbaric chambers—monoplace and multiplace. Monoplace chambers accommodate a single person. The patient enters the chamber, then it is closed, and the pressure is increased. The advantages of a monoplace chamber are that the patient does not have to wear a mask or a hood to receive the oxygen and the treatment regimen is designed specifically for each individual. The major disadvantages are that the patient is inaccessible to the staff during treatment should an emergency arise, and the pure oxygen atmosphere creates an increased fire hazard. In multiplace chambers, several patients use the same chamber simultaneously. Each person is given oxygen through a face mask or hood, but all patients receive the same treatment. A staff member remains in the chamber throughout the procedure.

Hyperbaric chambers can be associated with hospitals, but are increasingly part of free-standing clinics. Insurance may cover the cost of treatment for approved indications such as **carbon monoxide poisoning**, but may reject payment for uses that are considered experimental or controversial. The American Board of Medical Specialists certifies physician competency in the undersea medicine, including the use of hyperbaric chambers. The Baromedical Nurses Association offers three levels of certification for hyperbaric nurses, and the National Board of Hyperbaric Medicine Technology certifies hyperbaric technicians. Individuals considering hyperbaric therapy should

seek facilities run by health care providers credentialed by these organizations.

Preparation

No special preparation is needed to use a hyperbaric chamber other than educating patients about what to expect during treatment.

Aftercare

After HBOT is complete, a period of decompression in the chamber is required until the pressure in the chamber is equal to the pressure outside. Serious complications can occur if decompression occurs suddenly.

Risks

Hyperbaric chambers, because of their use of 100% oxygen, present a potential fire risk. In addition, although hyperbaric oxygen therapy is very safe when used correctly, complications can occur. Oxygen **poisoning**, also called oxygen toxicity, can occur when an individual is exposed to high doses of oxygen for a prolonged period. Excess oxygen causes chemical changes in the body that negatively affect cells and metabolic processes. Symptoms of oxygen poisoning include nausea, **vomiting**, dry **cough**, seizures, chest **pain**, sweating, muscle twitching, ringing of the ears, **hallucinations**, **dizziness**, **shortness of breath**, and a decreased level of consciousness.

Other complications can occur as the result of increased pressure within the chamber. These include pain and bloody discharge from congested sinuses, ear pain, rupture of the eardrum, and bleeding from the ear if the Eustachian tube that connects the ear to the back of the throat is clogged and pressure on either side of the eardrum is not equalized. Teeth that are infected or have been repaired may become painful or explode if gas is trapped within them. A few individuals develop pneumothorax. This is a serious condition where air is trapped between the lungs and the chest cavity.

Results

HBOT is expected to promote healing and improve the health of individuals with conditions for which it is approved.

Abnormal results

Under some conditions HBOT fails to cause improvement or complications occur.

Hyperbilirubinemia *see* **Neonatal jaundice**

Hypercalcemia

Definition

Hypercalcemia is an abnormally high level of **calcium** in the blood, usually more than 10.5 milligrams per deciliter of blood.

Description

Calcium plays an important role in the development and maintenance of bones in the body. It is also needed in tooth formation and is important in other body functions. Normally, the body maintains a balance between the amount of calcium in food sources and the calcium already available in the body's tissues. The balance can be upset if excess amounts of calcium are eaten or if the body is unable to process the mineral because of disease.

Calcium is one of the most important and most abundant **minerals** in the human body. Dairy products are the major source of calcium. Eggs, green leafy vegetables, broccoli, legumes, nuts, and whole grains provide smaller amounts. Only about 10–30% of the calcium in food is absorbed into the body. Most calcium is found in combination with other dietary components and must be broken down by the digestive system before it can be used. Calcium is absorbed into the body in the small intestine. Its absorption is influenced by such factors as the amount of **vitamin D**

WWW.BOOKBAZ.IR

hormone available to aid the process and the levels of calcium already present in the body. As much as 99% of the body's calcium is stored in bone tissue. A healthy person experiences a constant turnover of calcium as bone tissue is built and reshaped. The remaining 1% of the body's calcium circulates in the blood and other body fluids. Circulating calcium plays an important role in the control of many body functions, such as blood clotting, transmission of nerve impulses, muscle contraction, and other metabolic activities. In the bloodstream, calcium maintains a constant balance with another mineral, phosphate.

Two main control agents are vital in maintaining calcium levels, vitamin D hormone and parathyroid hormone. A hormone is a chemical substance that is formed in one organ or part of the body and carried in the blood to another organ. It can alter the function, and sometimes the structure, of one or more organs.

- Parathyroid hormone (PTH). The four parathyroid glands are endocrine glands located next to the thyroid gland in the neck. A gland is a cell or group of cells that produces a material substance (secretion). When the level of calcium circulating in the blood drops, the parathyroid gland releases its hormone. PTH then acts in three ways to restore the normal blood calcium level. It stimulates the absorption of more calcium in the intestine; it takes more calcium from the bone tissue, and it causes the kidneys to excrete more phosphate.
- Vitamin D hormone. This hormone works with parathyroid hormone to control calcium absorption and affects the deposit of calcium and phosphate in the bone tissue.

The kidneys also help to control calcium levels. Healthy kidneys can increase calcium excretion almost fivefold to maintain normal concentrations in the body. Hypercalcemia can occur when the concentration of calcium overwhelms the ability of the kidneys to maintain balance.

Causes and symptoms

Causes of hypercalcemia

Many different conditions can cause hypercalcemia; the most common are **hyperparathyroidism** and cancer.

PRIMARY HYPERPARATHYROIDISM. Primary hyperparathyroidism is the excessive secretion of parathyroid hormone by one or more of the parathyroid glands. It is the most common cause of hypercalcemia in the general population. Women have this condition more frequently than men do, and it is more common in older people. It can appear 30 or more years after radiation treatments to the neck. Ninety percent of the cases of primary hyperparathyroidism are caused by a non-malignant growth on the gland.

Hyperparathyroidism can also occur as part of a rare hereditary disease called multiple endocrine neoplasia. In this disease, tumors develop on the parathyroid gland.

CANCER. People with cancer often have hypercalcemia. In fact, it is the most common life-threatening metabolic disorder associated with cancer. Ten to 20 percent of all persons with cancer have hypercalcemia. Cancers of the breast, lung, head and neck, and kidney are frequently associated with hypercalcemia. It also occurs frequently in association with certain cancers of the blood, particularly malignant myeloma. It is seen most often in patients with tumors of the lung (25–35%) and breast (20–40%), according to the National Cancer Institute. Cancer causes hypercalcemia in two ways. When a tumor grows into the bone, it destroys bony tissue (osteolysis). When the bone is not involved, factors secreted by cancer cells can increase calcium levels (humoral hypercalcemia of malignancy). The two mechanisms may operate at the same time.

Because immobility causes an increase in the loss of calcium from bone, cancer patients who are weak and spend most of their time in bed are more prone to hypercalcemia. Cancer patients are often dehydrated because they take in inadequate amounts of food and fluids and often have **nausea and vomiting**. **Dehydration** reduces the ability of the kidneys to remove excess calcium from the body. Hormones and **diuretics** that increase the amount of fluid released by the body can also trigger hypercalcemia.

OTHER CAUSES. Other conditions can cause hypercalcemia. Excessive intake of vitamin D increases intestinal absorption of calcium. During therapy for peptic **ulcers**, abnormally high amounts of calcium **antacids** are sometimes taken. Over use of antacids can cause milk-alkali syndrome and hypercalcemia. Diseases such as Paget's, in which bone is destroyed or reabsorbed, can also cause hypercalcemia. As in cancer or **paralysis** of the arms and legs, any condition in which the patient is immobilized for long periods of time can lead to hypercalcemia due to bone loss.

Common symptoms

Many patients with mild hypercalcemia have no symptoms and the condition is discovered during routine laboratory screening. Gastrointestinal symptoms include loss of appetite, nausea, **vomiting**, **constipation**, and abdominal **pain**. There may be a blockage in the

bowel. If the kidneys are involved, the individual will have to urinate frequently during both the day and night and will be very thirsty. As the calcium levels rise, the symptoms become more serious. Stones may form in the kidneys and waste products can build up. Blood pressure rises. The heart rhythm may change. Muscles become increasingly weak. The individual may experience mood swings, confusion, **psychosis**, and eventually, **coma** and death.

Diagnosis

High levels of calcium in the blood are a good indication of hypercalcemia, but these levels may fluctuate. Calcium levels are influenced by other compounds in the blood that may combine with calcium. Higher calcium and lower phosphate levels may suggest primary hyperparathyroidism. The blood levels of protein (serum albumin) and parathyroid hormone (PTH) are also measured in the diagnosis of hypercalcemia. Too much PTH in the blood may indicate primary hyperparathyroidism. Levels of calcium and phosphate in the urine should also be measured. The medical history and physical condition of the individual must be taken into consideration, especially in the early stages of hypercalcemia when symptoms are mild.

Treatment

The treatment of hypercalcemia depends on how high the calcium level is and what is causing the elevation. Hypercalcemia can be life-threatening and rapid reduction may be necessary. If the patient has normal kidney function, fluids can be given by vein (intravenously) to clear the excess calcium. The amount of fluid taken in and eliminated must be carefully monitored. If the patient's kidneys are not working well, acute hemodyalysis is probably the safest and most effective method to reduce dangerous calcium levels. In this procedure, blood is circulated through tubes made of semi-permeable membranes against a special solution that filters out unwanted substances before returning the blood to the body.

Drugs such as furosemide, called loop diuretics, can be given after adequate fluid intake is established. These drugs inhibit calcium reabsorption in the kidneys and promote urine production. Drugs that inhibit bone loss, such as calcitonin, biphosphates, and plicamycin, are helpful in achieving long-term control. Phosphate pills help lower high calcium levels caused by a deficiency in phosphate. Anti-inflammatory agents such as **steroids** are helpful with some cancers and toxic levels of vitamin D.

Treatment of the underlying cause of the hypercalcemia will also correct the imbalance. Hyperparathyroidism is usually treated by surgical removal of one or more of the parathyroid glands and any tissue, other than the glands themselves, that is producing excessive amounts of the hormone.

The hypercalcemia caused by cancer is difficult to treat without controlling the cancer. Symptoms can be alleviated with fluids and drug therapy.

Prognosis

Surgery to remove the parathyroid glands and any misplaced tissue that is producing excessive amounts of hormone succeeds in about 90% of all cases. Outcome is also influenced by whether any damage to the kidneys can be reversed.

Mild hypercalcemia can be controlled through good fluid intake and the use of effective drugs.

Hypercalcemia generally develops as a late complication of cancer and the expected outlook is poor without effective anticancer therapy.

Prevention

People with cancer who are at risk of developing hypercalcemia should be familiar with early symptoms and know when to see a doctor. Good fluid intake (up to four quarts of liquid a day if possible), controlling nausea and vomiting, paying attention to fevers, and keeping physically active as much as possible can help prevent problems. Dietary calcium restriction is not necessary because hypercalcemia reduces absorption of calcium in the intestine.

Karen Ericson, RN

Hypercholesterolemia

Definition

Hypercholesterolemia refers to levels of **cholesterol** in the blood that are higher than normal.

Description

Cholesterol circulates in the bloodstream. It is an essential molecule for the human body. Cholesterol is

WWW.BOOKBAZ.IR

a molecule from which hormones and **steroids** are made. It is also used to maintain nerve cells. Between 75% and 80% of the cholesterol that circulates in a person's bloodstream is made in that person's liver. The remainder is acquired from outside sources. Cholesterol is found in animal sources of food. It is not found in plants.

Normal blood cholesterol level is a number derived by laboratory analysis. A normal or desirable cholesterol level is defined as less than 200 mg of cholesterol per deciliter of blood (mg/dL). Blood cholesterol is considered to be borderline when it is in the range of 200–239 mg/dL. Elevated cholesterol level is 240 mg/dL or above. Elevated blood cholesterol is considered to be hypercholesterolemia.

Cholesterol has been divided into two major categories: low-density lipoprotein (LDL), the so-called "bad" cholesterol, and high-density lipoprotein (HDL), the so-called "good" cholesterol. Diet, **exercise**, **smoking**, alcohol, and certain illnesses can affect the levels of both types of cholesterol. Eating a high fat diet will increase one's level of LDL cholesterol. Exercising and reducing one's weight will both increase HDL cholesterol and lower LDL cholesterol.

The most common cause of elevated serum cholesterol is eating foods that are rich in saturated fats or contain high levels of cholesterol. Elevated cholesterol also can be caused by an underlying disease that raises blood cholesterol levels such as **diabetes mellitus**, **kidney disease**, **liver disease**, or **hypothyroidism**. It also can be caused by an inherited disorder in which cholesterol is not metabolized properly by the body. **Obesity**, which generally results from eating a diet high in fat, also can lead to elevated cholesterol levels in the blood. This is because obesity itself leads the body to produce excessive amounts of cholesterol.

Hypercholesterolemia increases the risk of **heart disease**. Elevated levels of circulating cholesterol cause deposits to form inside blood vessels. These deposits, called plaque, are composed of fats deposited from the bloodstream. When the deposits become sufficiently large, they block blood vessels and decrease the flow of blood. These deposits result in a disease process called atherosclerosis, which can cause **blood clots** to form that will ultimately stop blood flow. If this happens in the arteries supplying the heart, a **heart attack** will occur. If it happens in the brain, the result is a **stroke** where a portion of brain tissue dies. Atherosclerosis causes more deaths from heart disease than any other single condition. Heart disease has been the leading cause of death in the United States for the past half century.

There is a syndrome called familial hypercholesterolemia. Affected persons have consistently high levels of LDL. This leads to early clogging of the coronary arteries. In turn this leads to a heart attack. Among affected males, a first heart attack typically occurs in their 40s to 50s. Approximately 85% of men with this disorder have experienced a heart attack by the time they reach 60 years of age. The incidence of heart attacks among women with this disorder also is increased. However, it is delayed 10 years compared to men. The incidence of familial hypercholesterolemia is seven out of 1,000 people.

Causes and symptoms

Hypercholesterolemia is silent. There are no symptoms that are obvious to the naked eye. It is diagnosed by a blood test or after a heart attack or stroke occurs.

Diagnosis

Hypercholesterolemia is diagnosed by using a blood test. A blood specimen is obtained after the patient does not eat or drink anything (except water) for 12 hours. The **fasting** is done to measure the LDL and HDL cholesterol, which can only be determined accurately in a fasting state. Some experts agree that an acceptable limit for LDL cholesterol as 130 mg/dL, though the National Cholesterol Education Program Adult Treatment Panel III recommended a goal of less than 100mg/dL. Total cholesterol of under 200 mg/dL is thought to be an acceptable range.

Treatment

If an individual's cholesterol is elevated, discussions with a physician should be scheduled to determine what course of treatment may be needed. Initial treatment for hypercholesterolemia usually requires dietary changes to reduce the intake of total fat, saturated fat, and cholesterol. Most health care professionals will recommend that a person's weight and height be proportionate. In addition to diet, guidelines recommend exercise to help bring weight and cholesterol to acceptable levels. Further, experts counsel persons with elevated blood cholesterol levels to increase their intake of soluble fiber. Sources of soluble fiber include bran, foods containing whole grains and other sources of indigestible fiber such as lignin. Physicians also recommend that patients with high cholesterol stop smoking as part of first-line therapy for hypercholesterolemia.

The reason for treating elevated cholesterol is to reduce an individual's risk of complications. If a diet low in cholesterol and saturated fats does not

significantly reduce a person's cholesterol level, medication may be required. For every 1% reduction in cholesterol level, the risk of heart disease is reduced by 2%. It also is possible to partially reverse atherosclerosis that has already occurred by aggressively lowering cholesterol levels with diet and medications.

Prescription drugs are available to help lower cholesterol levels in the blood. These may be used as first-line therapy in high-risk patients or after about three months of dietary and lifestyle therapy. Cholestyramine, cholestipol, lovastatin, simvastatin, pravastatin, fluvaststin, rosuvastatin, and gemfibrazol are some of the drugs approved for use in the United States. The most often prescribed group of drugs are the statins, which also have been shown in some studies to reduce risk of depression and **dementia**.

Alternatives

There are advocates of treatment using **vitamins**, **minerals** and antioxidant substances in relatively high amounts. These amounts generally exceed those provided by the Food and Drug Administration in its Minimum Daily Requirements (MDR). Advocates of such therapies also emphasize increased levels of exercise, attaining an ideal body weight and increasing levels of fiber in one's diet.

Some people have advocated the use of garlic, soy and isoflavones to lower serum cholesterol levels. In 2003, enriched green tea was found to be an effective addition to a low-fat diet for lowering LDL cholesterol in adults.

Prognosis

The prognos is in direct proportion to serum cholesterol levels. People with hypercholesterolemia are at high risk of dying from heart disease.

Many studies have looked at the relationship between elevated cholesterol levels, increased risk for heart attack and death. In one investigation of relatively young males who had no known heart disease, cholesterol levels were measured and participants were followed for six years. During this time, all heart attacks and deaths that occurred among participants were recorded. As serum cholesterol levels increased, so did the risk of experiencing a fatal heart attack. The risk of a fatal heart attack was approximately five times higher among persons having cholesterol levels of 300 mg/dL or more compared to those with cholesterol levels below 200 mg/dL.

The Framingham Heart Study is an ongoing research effort. Cholesterol levels, smoking habits, heart attack rates, and deaths in the population of an entire town have been recorded for over 40 years. After 30 years, more than 85% of persons with cholesterol levels of 180 mg/dL or less were still alive; almost a third of those with cholesterol levels greater than 260 mg/dL had died.

Prevention

Experts suggest the following steps to maintain serum cholesterol within normal limits: an important component is to maintain a normal weight for height and to reduce one's weight if it is inappropriate for height. Changing dietary habits by reducing the amount of fat and cholesterol consumed is advised. Doctors recommend avoiding smoking by not starting or quitting if currently a smoker. Increasing levels of fiber in the diet by including foods such as beans, raw fruits, whole grains and vegetables is receommended. It is important to exercise on a regular basis. Aerobic exercise is especially helpful in reducing serum cholesterol levels.

People from families with a strong history of early heart attacks should be evaluated with a lipid screen. Proper diet, exercise and the use of effective drugs can reduce serum lipid levels.

Nutrition and cardiac experts offer the following suggestions:

- purchasing low-fat or fat-free dairy products such as milk, cheese, sour cream, and yogurt
- eating lean red meats, chicken without skin, and fish
- reducing consumption of foods high in saturated fat such as french fries
- avoiding foods that are rich sources of cholesterol such as eggs, liver, cheese, and bacon
- eating smaller servings
- keeping a food journal and writing down everything eaten each day
- preparing food by microwaving, boiling, broiling, or baking food instead of frying
- trimming the fat from meat before cooking it.

Hypercoagulation disorders

Definition

Hypercoagulation disorders (or hypercoagulable states or disorders) have the opposite effect of the more common **coagulation disorders**. In hypercoagulation, there is an increased tendency for clotting of the blood, which may put a patient at risk for obstruction of veins and arteries (phlebitis or **pulmonary embolism**).

Description

In normal hemostasis, or the stoppage of bleeding, clots form at the site of the blood vessel's injury. The difference between that sort of clotting and the clotting present in hypercoagulation is that these clots develop in circulating blood.

This disorder can cause clots throughout the body's blood vessels, sometimes creating a condition known as thrombosis. Thrombosis can lead to infarction, or death of tissue, as a result of blocked blood supply to the tissue. However, hypercoagulability does not always lead to thrombosis. In **pregnancy** and other hypercoagulable states, the incidence of thrombosis is higher than that of the general population, but is still under 10%. In association with certain genetic disorders, hypercoagulation disorders may be more likely to lead to thrombosis. Hypercoagulation disorders are also known as hyperhomocystinemia, antithrombin III deficiency, factor V leyden, and protein C or protein S deficiency.

Causes and symptoms

Hypercoagulation disorders may be acquired or hereditary. Some of the genetic disorders that lead to hypercoagulation are abnormal clotting factor V, variations in fibrinogen, and deficiencies in proteins C and S. Other body system diseases may lead to these disorders, including diabetes, sickle cell anemia, **congenital heart disease**, lupus, **thalassemia**, polycythemia rubra vera, and others.

Antithrombin III deficiency is a hereditary hypercoagulation disorder that affects both sexes. Symptoms include obstruction of a blood vessel by a clot (thromboembolic disease), vein inflammation (phlebitis), and **ulcers** of the lower parts of the legs.

The role of proteins C and S is a complex one. In order for coagulation to occur, platelets (small, round fragments in the blood) help contract blood vessels to lessen blood loss and to help plug damaged blood vessels. The conversion of platelets into actual clots is a complicated web involving proteins that are identified clotting factors. The factors are carried in the plasma, or liquid portion of the blood. Proteins C and S are two of the clotting factors present in the plasma to help regulate or activate parts of the clotting process. Protein C is considered an anticoagulant. Mutation defects in the proteins may decrease their concentrations in the blood, and may or may not affect their resulting anticoagulant activity.

Factor V is an unstable clotting factor present in plasma. Abnormal factor V resists the changes that normally occur through the influence of protein C, which can also lead to hypercoagulability. Prothrombin, a glycoprotein that converts to thrombin in the early stage of the clotting process, is affected by

the presence of these proteins, as well as other clotting factors.

Diagnosis

Examination

The diagnosis of hypercoagulation disorders is completed with a combination of **physical examination**, medical history, and blood tests. An accurate medical history is important to determine possible symptoms and causes of hypercoagulation disorders.

Tests

There are a number of blood tests that can determine the presence or absence of proteins, clotting factors, and platelet counts in the blood. Among the tests used to detect hypercoagulation is the Antithrombin III assay. Protein C and Protein S concentrations can be diagnosed with immunoassay or plasma antigen level tests.

Treatment

Warfarin (Coumadin) and heparin anticoagulants may be administered to reduce the clotting effects and maintain fluidity in the blood. Heparin is an anticoagulant that prevents thrombus formation and is used primarily for liver and lung clots. Heparin works right away, keeping **blood clots** from growing. It usually is injected. In recent years, more physicians have been prescribing low-molecular weight heparin, purified versions of the drug that can be given with less monitoring such as enoxaparin (Lovenox). Warfarin often is used for long-term treatment of blood clots and is taken orally. Patients must work closely with their physicians to constantly monitor its effects and adjust dose if necessary. Too little warfarin can lead to clotting, but too much can thin the blood so much that life-threatening bleeding can occur. The same can be true of low-molecular weight heparin when used on a long-term, at-home basis.

Prognosis

The prognosis for patients with hypercoagulation disorders varies depending on the severity of the clotting and thrombosis. If undetected and untreated, thrombosis could lead to recurrent thrombosis and pulmonary **embolism**, a potentially fatal problem.

Prevention

Hereditary hypercoagulation disorders may not be prevented. Genetic and blood testing may help determine a person's tendency to develop these disorders.

KEY TERMS

Blood clot—A thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

Embolism—The blockage of a blood vessel by air, blood clot, or other foreign body.

Embolus—A clot that has formed in a blood vessel somewhere in the body, often in the heart. It can break away from the wall of the vessel where it was formed, travel through the circulatory system, and become wedged in the brain, causing an embolic stroke. Ischemic strokes can be caused by the formation of a blood clot in one of the cerebral arteries (arteries supplying blood to the brain). If the clot grows large enough it will block blood flow.

Plaque—A deposit, usually of fatty material, on the inside wall of a blood vessel.

Thrombosis—The formation or development of a blood clot or thrombus.

Hyperemesis gravidarum

Definition

Hyperemesis gravidarum means excessive **vomiting** during **pregnancy**.

Description

In pregnant women, **nausea and vomiting** (morning sickness) are common, affecting up to 80% of pregnancies. Hyperemesis, or extreme nausea and excessive vomiting, occur in about 1% of pregnancies. This condition causes uncontrollable vomiting, severe **dehydration**, and weight loss for the mother. However, hyperemesis gravidarum rarely causes problems for the unborn baby.

Causes and symptoms

The cause of nausea and vomiting during pregnancy is unknown but may be related to the level of certain hormones produced during pregnancy. Hyperemesis is seen more often in first pregnancies and multiple pregnancies (twins, triplets, etc.). The main symptom of hyperemesis is severe vomiting, which causes dehydration and weight loss.

Diagnosis

Although many women with morning sickness feel like they are vomiting everything they eat, they continue to gain weight and are not dehydrated; they do not have hyperemesis gravidarum. Women with this condition will start to show signs of **starvation**, including weight loss. **Physical examination** and laboratory tests of blood and urine samples will be used to help diagnose the condition. One of the most common tests used to help diagnosis and monitor hyperemesis gravidarum is a test for ketones in the urine. Excessive ketones in the urine (ketonuria) indicate that the body is not using carbohydrates from food as fuel and is inadequately trying to break down fat as fuel. Ketonuria is a sign that the body is beginning to operate in starvation mode.

Treatment

Hospitalization is often required. Intravenous fluids with substances that help the body conduct nerve signals (electrolytes) may be given to correct the dehydration and excessive acid in the blood (acidosis). Anti-nausea or sedative medications may be given by injection to stop the vomiting. In some cases, oral medication may be prescribed to control the nausea and vomiting while food is reintroduced. If food cannot be tolerated at all, intravenous **nutritional supplements** may be necessary. Injections of vitamin B_6, in particular, may help overcome nutritional deficiencies that often occur.

Alternatives

The severe vomiting associated with hyperemesis gravidarum requires medical attention. Milder episodes of nausea or vomiting may be reduced with deep breathing and relaxation exercises. The use of herbal remedies should be done with extreme caution during pregnancy, especially in the first trimester. Natural remedies to reduce nausea include a teaspoon of cider vinegar in a cup of warm water, or tea made from anise (*Pinpinella anisum*), fennel seed (*Foeniculum vulgare*), red raspberry (*Rubus idaeus*), or ginger (*Zingiber officinale*). Wristbands can be positioned over **acupressure** points on both wrists. **Aromatherapy** with lavender, rose, or chamomile can be soothing, as can smelling ground ginger. Homeopathic remedies—which use extremely diluted solutions as treatments—can be safe and effective for controlling symptoms in some women.

Prognosis

In virtually all cases, the pregnancy can continue to the successful delivery of a healthy baby.

Prevention

Although there is no evidence that hyperemesis gravidarum can be prevented, vomiting during pregnancy sometimes may be lessened. Maintaining a healthy diet, getting adequate sleep, and controlling **stress** may contribute to prevention or improvement of symptoms. Several strategies may help lessen the nausea and vomiting. Eating dry foods and limiting fluid intake may also be helpful. Small meals should be eaten frequently throughout the day, with a protein snack at night. Eating soda crackers before rising from bed in the morning may help prevent early morning nausea. Iron supplements may cause nausea and can be eliminated until the nausea is controlled. Sitting upright for 45 minutes after meals may also help.

Hyperglycemia

Definition

Hyperglycemia is an abnormally high level of glucose (sugar) in the blood, which occurs when the body has too little insulin or cannot utilize insulin properly. Hyperglycemia is usually associated with **diabetes mellitus** but transient hyperglycemia can be also caused by pregnancy, illness, injury, or other stresses. Prolonged hyperglycemia can damage multiple organ systems.

Demographics

Reported cases of diabetes, which is the primary cause of hyperglycemia, have increased at least two-fold over the past two decades in most parts of the world. The incidence of diabetes varies greatly, both in neighboring regions with differing lifestyles and in countries with genetically similar populations. The annual incidence ranges from 0.61 cases per 100,000 people in China to 41.4 cases per 100,000 in Finland. The incidence of diabetes appears to increase with distance from the equator.

In 2007 it was estimated that 7.8% of Americans have diabetes, of which approximately 24% are undiagnosed, and the incidence continues to rise. In addition 3–8% of American women develop gestational diabetes during pregnancy.

The majority of new diabetes cases in children are type 1, formerly known as juvenile–onset diabetes. Although type 1 can develop at any age, its incidence increases with age until mid-puberty and then declines. Caucasians have the highest rate of type 1 diabetes and Chinese have the lowest rate. Type 1 diabetes is 1.5 times as likely to develop in American whites as in American blacks or Hispanics. Evidence suggests that when immigrants move to an area with a higher incidence of type 1 diabetes, their rates of diagnosis increase. Furthermore, children are increasingly being diagnosed with type 2 diabetes, formerly known as adult-onset. This trend is particularly true for children from ethnic and racial minorities. Diabetic adolescents are especially susceptible to hyperglycemia, both because of fluctuating hormone levels and because many adolescents have erratic eating and sleeping patterns.

Hyperglycemia often goes untreated. A recent study from Detroit reported that 41% of people with sustained hyperglycemia failed to get appropriate treatment within six months. Another 25% went one year without treatment and 11% failed to get appropriate care for up to two years.

Description

Insulin, a hormone produced by the pancreas, is required for the processing of carbohydrates, fats, and proteins. Insulin reduces blood glucose levels by:

- enabling glucose to enter muscle cells
- stimulating glycogenesis—the conversion of glucose to glycogen for storage
- inhibiting glycogenolysis—the release of stored glucose from liver glycogen
- inhibiting gluconeogenesis—the breakdown of protein and fat for glucose in the liver and kidneys

Hyperglycemia (high blood sugar symptoms)	Hypoglycemia (low blood sugar symptoms)
• Fatigue	• Shakiness
• High levels of sugar in urine	• Dizziness
• Frequent urination	• Sweating
• Increased thirst	• Hunger
• Hunger	• Headache
• Blurry vision	• Sudden moodiness or behavior changes
• Impotence (male)	• Clumsy or jerkey movements
• Unintentional weight loss	• Seizure
• Tingling or numbness in hands or feet	• Difficulty paying attention, or confusion
	• Tingling sensations around the mouth

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

WWW.BOOKBAZ.IR

- slowing the breakdown of fat to triglycerides, free fatty acids, and ketones
- stimulating fat storage

Deficiencies in the production or utilization of insulin cause hyperglycemia because circulating glucose is not used or stored and gluconeogenesis continues unabated. The excess glucose overwhelms the kidneys, causing increased urination (osmotic diuresis), excess sugar in the urine (glycosuria), thirst, and **dehydration**. Because the body cannot utilize glucose, fats and proteins are broken down for energy, producing ketones as waste products that are excreted in the urine. In the absence of insulin, ketone build-up in the blood leads to diabetic ketoacidosis (DKA) and potentially to a life-threatening diabetic coma. Children with type 1 diabetes who develop DKA can waste away and die.

All diabetics have occasional episodes of hyperglycemia—which is usually detected by regularly checking their blood sugar levels—and hyperglycemia is a major cause of diabetes-related complications. Hyperglycemia impairs immunity and can make patients susceptible to recurrent infections, particularly infections of the skin and urinary and respiratory tracts. Serious, long–term consequences of prolonged hyperglycemia depend on a variety of factors and usually develop later in life. These complications include nerve damage and diabetic neuropathy, **stroke** blindness, and the need for amputations.

Persistent hyperglycemia during pregnancy can lead to fetal **gigantism** premature delivery, and increased infant morbidity and mortality. DKA during pregnancy may result in fetal death. Sick infants often have low amounts or poorly functioning insulin, which can lead to hyperglycemia.

Risk factors

Type 1 diabetes is usually due to inherited factors that affect insulin production. Diabetes in newborns is usually related to an inherited defect in a potassium channel in the cells that secrete insulin. Risk factors for type 2 diabetes include gestational diabetes during pregnancy, advancing age, obesity, and a sedentary lifestyle.

Risk factors for untreated or delayed treatment of hyperglycemia in diabetics include:

- poor control of blood glucose over time
- lower income levels or poverty
- poor adherence to medication
- absence of regular physician visits
- higher prescription drug co-payments

Causes and symptoms

Hyperglycemia is usually caused by:

- insufficient insulin administration by type 1 diabetics
- insulin ineffectiveness in type 2 diabetics
- diabetics who eat more or exercise less than they planned
- stress from illness, even a minor infection such as a cold or flu
- acute stress from trauma, heart attack, or stroke
- emotional stresses from family, school, work, or relationship problems

Hyperglycemia is sometimes caused by other factors, conditions, or diseases including:

- excessive food intake
- metabolic syndrome
- pregnancy
- drugs, including corticosteroids, tricyclic antidepressants, diuretics, epinephrine, estrogens in birth control pills or hormone replacement therapies, lithium, phenytoin (Dilantin), salicylates, beta–blockers such as metoprolol
- liver problems
- hyperthyroidism
- acromegaly—growth hormone overproduction
- Cushing's syndrome
- chronic renal failure
- pancreatitis
- pancreatic cancer

Hyperglycemia in newborns can result from glucose infusions given to low-birth-weight infants or from physiological stress associated with surgery, **respiratory distress syndrome** or sepsis.

Although some diabetics never experience symptoms of hyperglycemia, most experience hyperglycemic symptoms even before they are diagnosed with diabetes. It is important to recognize the symptoms of hyperglycemia so that it can be treated quickly:

- frequent urination
- severe thirst
- frequent hunger
- hunger even after eating
- weakness
- fatigue
- blurred vision
- rapid weight loss
- nausea
- vomiting

- dry mouth
- itchy skin
- impotence
- hyperventilation—breathing faster and deeper
- abnormal heart rate
- confusion
- coma
- recurrent infections or poor wound healing with chronic hyperglycemia

The primary symptoms of hyperglycemia in children are usually increased frequency of urination and increased urine volume. This can lead to nighttime urination and incontinence, but may be overlooked in infants due to their high fluid intake and diaper use. Babies often have no noticeable symptoms. Some children with hyperglycemia become irritable or ill-tempered and experience general malaise, **headache** and weakness.

Diabetics can develop DKA at lower blood sugar levels when they are ill; thus DKA is most often triggered by infection. In children with type 1 diabetes, DKA usually develops gradually over a few days as blood sugar levels rise. However, DKA can develop in less than 24 hours. Frequent urination and increased thirst are the first signs of DKA. Other symptoms include:

- flushed face
- headache
- shortness of breath
- deep, labored breathing
- fruity smelling breath from ketones
- abdominal pain, especially in children
- nausea and vomiting
- dry skin
- very dry mouth
- severe dehydration
- blurred vision
- rapid heartbeat
- drowsiness and lethargy
- coma

Hyperglycemic hyperosmolar syndrome (HHS) is a life-threatening complication of type 2 diabetes, characterized by extremely high blood glucose levels without ketone production, severe dehydration, and reduced consciousness. The blood becomes thick with glucose, salts, and other substances (hyperosmolarity). It may be brought on by infection or other illness or medications.

KEY TERMS

Diabetic hyperglycemic hyperosmolar syndrome; HHS—A life–threatening complication of type 2 diabetes in which blood sugar levels are extremely high.

Diabetic ketoacidosis; DKA—A serious complication of diabetes in which organic compounds called ketones reach very high levels in the blood.

Glycogen—A polysaccharide that is the principal source of stored glucose in humans.

Glycosuria—Abnormal amounts of sugar in the urine.

Insulin—A protein hormone synthesized in the pancreas and secreted by beta cells of the islets of Langerhans. Insulin is required for the metabolism of carbohydrates, lipids, and proteins, and regulates blood sugar levels by facilitating the uptake of glucose into tissues, converting sugars to glycogen, fatty acids, and triglycerides, and preventing the release of glucose from the liver.

Ketones—Organic compounds that build up in the blood and urine from the breakdown of fat and that are poisonous at high levels.

Osmotic diuresis—Increased urination caused by sugar or other substances in the urine.

Diagnosis

Tests

Hyperglycemia is diagnosed by measuring blood glucose levels. In non-pregnant adults the normal range for blood glucose before a meal (fasting) is 70–130 mg/dL of blood. A normal non–fasting blood glucose level is less than 180 mg/dL or 9 nanomoles (nm) per liter (L). A non-fasting blood glucose concentration above 200 mg/dL or 11 nm/L is diagnostic of diabetes. Glycosuria occurs at blood glucose levels above 180 mg/dL. Physicians often individualize blood glucose goals for each patient.

The A1C test measures average blood-glucose levels over two to three months. Non-diabetics score at about 5% on the A1C test. The American Diabetes Association (ADA) recommends that most people with diabetes keep their A1C levels at or below 7%.

Routine urinalysis includes a measure of glucose in the urine. With normal kidney function glucose is

WWW.BOOKBAZ.IR

found in the urine only when it is abnormally high in the blood. Ketones in the urine are measured when blood glucose is over 240 mg/dL.

Treatment

Traditional

The standard treatment for hyperglycemia is injection of insulin, usually in combination with intravenous fluids and salts (electrolytes). DKA is treated with insulin, electrolytes, and fluids. In children and adolescents, these components must be carefully adjusted for the patient's weight and administered with great precision. HHS is treated with fluids, potassium, and insulin. DKA and HHS usually require hospitalization.

Home remedies

Diabetics can often lower their blood sugar by exercising and/or eating less food. However, if ketones are present in the urine, **exercise** can increase blood sugar.

Prognosis

The long-term consequences of prolonged hyperglycemia can include:

- intellectual impairment in children under four years of age
- increased susceptibility to infection
- retinopathy or blindness
- cataracts
- progressive kidney failure
- high blood pressure
- peripheral vascular disease
- early coronary artery disease
- nerve damage including peripheral and autonomic neuropathy

Age-specific mortality from diabetic hyperglycemia is probably twice that of the general population. Most deaths result from delayed diagnosis or from neglected treatment. The overall mortality rate from DKA is 1.2–9%. Children aged 1–4 years and adolescents are at particularly high risk for cerebral edema (swelling) from DKA. Of the one percent of children with DKA who develop cerebral edema, 57% recover completely, 21% have some type of neurological damage, and 21% die. The mortality rate from HHS may be as high as 40%.

Prevention

Prevention requires good diabetes management, careful monitoring of blood sugar levels, and early detection and correction of hyperglycemia. Hyperglycemia with type 1 diabetes can be prevented by carefully balancing dietary intake, physical activity, and insulin administration. Women are usually screened for gestational diabetes between the 24th and 28th week of pregnancy.

Concerns

Parents of a diabetic child may live with the uncertainty of possible hyperglycemic episodes but can be reassured by knowing that continuous glucose monitoring, a proper diet as advised by the pediatrician, insulin therapy if prescribed, and appropriate exercise can control the disease and help avoid extremes that lead to hyperglycemia. It is important to maintain close contact with the child's diabetes team of professionals and to learn as much as possible about the disease and the symptoms to watch for in the child that may signal hyperglycemia. The parents of school-age children should make sure that teachers also understand the warning signs of hyperglycemia so that immediate medical attention can be given when needed.

Hyperhidrosis

Definition

Hyperhidrosis is a disorder marked by excessive sweating. It usually begins at **puberty** and affects the palms, soles, and armpits.

Description

Sweating is the body's way of cooling itself and is a normal response to a hot environment or intense **exercise**. Excessive sweating unrelated to these conditions can be a problem for some people. Those with constantly moist hands may feel uncomfortable shaking hands or touching, while others with sweaty armpits and feet may have to contend with the unpleasant odor that results from the bacterial breakdown of sweat and cellular debris (bromhidrosis). People with hyperhidrosis often must change their clothes at least once a day, and their shoes can be ruined by the excess moisture. Hyperhidrosis may contribute to such skin diseases as athlete's foot (tinea pedis) and **contact dermatitis**.

In addition to excessive sweat production, the texture and color of the skin itself may be affected by hyperhidrosis. The skin may turn pink or bluish white. Severe hyperhidrosis of the soles of the feet may produce cracks, fissures, and scaling of the skin.

Hyperhidrosis in general and axillary hyperhidrosis (excessive sweating in the armpits) in particular are more common in the general population than was previously thought. A group of dermatologists in Virginia reported in 2004 that 2.8% of the United States population, or about 7.8 million persons, have hyperhidrosis. Of this group, slightly more than half (4 million persons) have axillary hyperhidrosis. One-third of the latter group, or about 1.3 million persons, find that the condition significantly interferes with daily activities and is barely tolerable. Only 38% had ever discussed their excessive sweating with their doctor.

KEY TERMS

Dermatitis—A skin condition characterized by a red, itchy rash. It may occur when the skin comes in contact with something to which it is sensitive.

Causes and symptoms

There are three basic forms of hyperhidrosis: emotionally induced; localized; and generalized. Emotionally induced hyperhidrosis typically affects the palms of the hands, soles of the feet, and the armpits. Localized hyperhidrosis typically affects the palms, armpits, groin, face, and the area below the breasts in women, while generalized hyperhidrosis may affect the entire body.

Hyperhidrosis may be either idiopathic (of unknown cause) or secondary to **fever**, metabolic disorders, **alcoholism**, **menopause**, **Hodgkin's lymphoma**, **tuberculosis**, various types of cancer, or the use of certain medications. The medications most commonly associated with hyperhidrosis are propranolol, venlafaxine, tricyclic antidepressants, pilocarpine, and physostigmine.

Most cases of hyperhidrosis begin during childhood or adolescence. Hyperhidrosis that begins in adult life should prompt the doctor to look for a systemic illness, medication side effect, or metabolic disorder.

Hyperhidrosis affects both sexes equally and may occur in any age group. People of any race may be affected; however, for some unknown reason, Japanese are affected 20 times more frequently than members of other ethnic groups.

Diagnosis

Hyperhidrosis is diagnosed by patient report and a **physical examination**. In many cases the physician can directly observe the excessive sweating.

WWW.BOOKBAZ.IR

Tests

The doctor may perform an iodine starch test, which involves spraying the affected areas of the patient's body with a mixture of 500 g of water-soluble starch and 1 g iodine crystals. Areas of the skin producing sweat turn black.

The doctor will order other laboratory or imaging tests if he or she suspects that the sweating is associated with another disease or disorder.

Treatment

Most over-the-counter antiperspirants are not strong enough to effectively prevent hyperhidrosis. To treat the disorder, doctors prescribe 20% aluminum chloride hexahydrate solution (Drysol). It is applied at night to the affected areas and then wrapped in a plastic film until morning. Drysol works by blocking the sweat pores. Formaldehyde and glutaraldehyde-based solutions can also be prescribed; however, formaldehyde may trigger an allergic reaction and glutaraldehyde can stain the skin (for this reason it is primarily applied to the soles).

Drugs

Anticholinergic drugs may be given. These drugs include such medications as propantheline, oxybutynin, and benztropine.

Injections of botulinum toxin (Botox) under the skin work well for some patients. Botox works to stop the excessive sweating by preventing the transmission of nerve impulses to the sweat glands. These injections must be repeated every 4–12 months.

Alternatives

An electrical device that emits low-voltage current can be held against the skin to reduce sweating. These treatments are usually conducted in a doctor's office on a daily basis for several weeks, followed by weekly visits. Dermatologists recommend that patients wear clothing made of natural or absorbent fabrics, avoid high-buttoned collars, use talc or cornstarch, and keep underarms shaved.

The only permanent cure for hyperhidrosis of the palms is a surgical procedure known as a **sympathectomy**. To treat severe excessive sweating, a surgeon can remove a portion of the nerve near the top of the spine that controls palm sweat. Few neurosurgeons in the United States will perform the procedure because it often results in compensatory sweating in other regions of the body. Alternatively, it is possible to surgically remove the sweat gland-bearing skin of the armpits, but this is a major procedure that may require skin grafts.

More recently, **liposuction** under the armpits has been successfully used to treat hyperhidrosis in this region of the body. The liposuction removes some of the excess sweat glands responsible for axillary hyperhidrosis. The procedure also has the advantage of leaving smaller **scars** and being less disruptive to the overlying skin.

Prognosis

Hyperhidrosis is not associated with increased mortality; it primarily affects the patient's quality of life rather than longevity. While the condition cannot be cured without radical surgery, it can usually be controlled effectively.

Hyperkalemia

Definition

Hyperkalemia refers to serum or plasma levels of potassium ions above 5.5 mEq/L. The concentration of potassium is often expressed in units of milliequivalents per liter (mEq/L). The normal concentration of potassium in the serum is in the range of 3.5–5.0 mEq/L.

Description

A normal adult who weighs about 150 lb. (70 kg) contains a total of about 3,500 mEq of potassium stores in the body. Most of this potassium (about 98%) occurs inside various cells (intracellular) and organs, where its concentration is about 150 mEq/L. This level is in contrast to the much lower concentration found in the blood serum, where only about 0.4% of the body's potassium resides. Hyperkalemia can be caused by an overall excess of body potassium, or by a shift from inside to outside cells. For example, hyperkalemia can be caused by the sudden release of potassium ions from muscle into the surrounding fluids.

In a normal person, hyperkalemia from too much potassium in the diet is prevented by at least three types of regulatory processes. First, various cells and organs act to prevent hyperkalemia by taking up potassium from the blood. It is also prevented by the action of the kidneys, which excrete potassium into the urine. A third protective mechanism is **vomiting**. Consumption of a large dose of potassium ions, such as potassium chloride, induces a vomiting reflex to expel most of the potassium before it can be absorbed.

Causes and symptoms

Hyperkalemia can occur from a variety of causes, including the consumption of too much of a potassium salt; failure of the kidneys to normally excrete potassium ions into the urine; leakage of potassium from cells and tissues into the bloodstream; and from acidosis. The most common cause of hyperkalemia is kidney (or renal) disease, which accounts for about three-quarters of all cases. Kidney function is measured by the glomerular filtration rate, the rate at which each kidney performs its continual processing and cleansing of blood. The normal glomerular filtration rate is about 100 mL/min. If the kidney is damaged so that the glomerular filtration rate is only 5 mL/min or less, hyperkalemia may result, especially if high-potassium foods are consumed. The elderly are at particular risk, since many regulatory functions of the body may not work as efficiently in this population. Elderly patients who are being treated with certain drugs for high blood pressure, such as spironolactone (Aldactone) and triamterene (Dyazide), must be monitored for possible hyperkalemia as these medications promote the retention of potassium by the kidneys.

Hyperkalemia can also be caused by a disease of the adrenal gland called Addison's disease. The adrenal gland produces the hormone aldosterone that promotes the excretion of potassium into the urine by the kidney.

Injury to muscle or other tissues, including severe **burns** or infections, can also lead to hyperkalemia. Since most of the potassium in the body is contained in muscle, a severe **trauma** that crushes muscle cells results in an immediate increase in the concentration of potassium in the blood.

Acidic blood plasma, or acidosis, is an occasional cause of hyperkalemia. Acidosis, which occurs in a number of diseases, is defined as an increase in the concentration of hydrogen ions in the bloodstream. In the body's attempt to correct the situation, hydrogen is taken up by muscle cells out of the blood in an exchange mechanism involving the transfer of potassium ions into the bloodstream. This can abnormally elevate the plasma's concentration of potassium ions. When acidosis is the cause of hyperkalemia, treating the patient for acidosis has two benefits: a reversal of both the acidosis and the hyperkalemia.

Symptoms of mild to moderate hyperkalemia are often vague. Many cases of hyperkalemia are discovered incidentally as a result of routine blood laboratory testing. Heart abnormalities of mild hyperkalemia (5.5 to 6.0 mEq/L potassium) can be detected by an electrocardiogram (ECG or EKG). With severe hyperkalemia (over 7.0 mEq/L potassium), the heart may beat at a dangerously rapid rate (fibrillation) or stop beating entirely (cardiac arrest). Patients with moderate or severe hyperkalemia may also develop nervous system symptoms such as tingling of the skin, numbness of the hands or feet, weakness, or a flaccid **paralysis**, which is characteristic of both hyperkalemia and **hypokalemia** (low plasma potassium).

Diagnosis

The patient's medical history is often an invaluable tool in helping to diagnose hyperkalemia. A history of kidney problems, trauma that involves crushing injuries, burns, consumption of medications that cause the body to retain potassium, and/or consumption of high potassium foods, particularly if

WWW.BOOKBAZ.IR

KEY TERMS

Acidosis—A medical condition caused by an increase in the concentration of hydrogen ions in the blood. The result of this increase is a lowered (acidic) blood pH level.

Potassium—A chemical element; also referred to as an electrolyte, which is predominantly found inside cells of the body (intracellular). Small changes in potassium levels can have pronounced effects on the cardiovascular and neuromuscular systems.

kidney function is impaired, may prompt a diagnosis of hyperkalemia.

Tests

Hyperkalemia can be measured by acquiring a sample of blood to measure the concentration of potassium ions in the bloodstream.

Procedures

Since high or low potassium levels result in abnormalities in heart function, an EKG is usually the method of choice for the diagnosis of both hyperkalemia and hypokalemia. Specific EKG changes often correlate with the level of hyperkalemia.

Treatment

Traditional

Patients with severe or symptomatic hyperkalemia should have intravenous access initiated, be placed on a cardiac monitor for observation of EKG changes, and should be admitted to an intensive care unit (ICU) for continuous observation and treatment to quickly lower potassium levels.

Drugs

If life-threatening EKG abnormalities are noted, a rapid reduction in potassium levels can be achieved by treatment with electrolyte supplementscalcium chloride or **calcium** gluconate. Onset of action is typically within five minutes. Patients receiving this treatment should be monitored continually by means of a cardiac monitor.

Insulin injections are used to treat hyperkalemia in emergency situations. Insulin is a hormone well-known for its ability to stimulate the entry of sugar (glucose) into cells. It also provokes the uptake of potassium ions by cells, decreasing potassium ion concentration in the blood. When insulin is used to treat hyperkalemia, glucose is also injected. Serum potassium levels begin to decline within 30–60 minutes and remain low for several hours.

In non-emergency situations, hyperkalemia can be treated with a low potassium diet in some individuals. If this does not succeed, the patient can be given a special resin to bind potassium ions. One such resin, **sodium** polystyrene sulfonate (Kayexalate), remains in the intestines where it absorbs potassium and forms a complex of resin and potassium. This complex is excreted in the feces. A typical dose of resin is 15 g, taken one to four times per day. The correction of hyperkalemia with resin treatment takes at least 24 hours. However, recent research seems to indicate that use of sodium polystyrene sulfonate to treat hyperkalemia may not as effective as once thought in lowering potassium levels and may increase risk for **necrosis** in the large intestine.

Prognosis

The prognosis for specifically correcting hyperkalemia is excellent. However, hyperkalemia is usually caused by kidney failure, an often irreversible and eventually fatal condition.

Prevention

Most healthy people are not at risk for hyperkalemia. Patients with renal disease and those on certain diuretic medications must be monitored to prevent its occurrence.

Hyperlipoproteinemia

Definition

Hyperlipoproteinemia occurs when there is too much lipid (fat) in the blood. Shorter terms that mean the same thing are hyperlipidemia and hyperlipemia. Dyslipidemia refers to a redistribution of **cholesterol** from one place to another that increases the risk of **vascular disease** without increasing the total amount of cholesterol. When more precise terms are needed, **hypercholesterolemia** and hypertriglyceridemia are used.

Description

It is commonly known that oil and water do not mix unless another substance like a detergent is added. Yet the body needs to transport both lipids (fats) and water-based blood within a single circulatory system. There must be a way to mix the two so that essential fatty nutrients can be transported in the blood and so that fatty waste products can be carried away from tissues. The solution is to combine the lipids with protein to form water-soluble packages that can be transported in the blood.

These packages of fats are called lipoproteins. They are a complex mixture of **triglycerides**, cholesterol, phospholipids, and special proteins. Some of these chemicals are fatty nutrients absorbed from the intestines on their way to being made part of the body. Cholesterol is a waste product on its way out of the body through the liver, the bile, and ultimately the bowel for excretion. The proteins and phospholipids make the packages water-soluble.

There are five different sizes of these chemical packages. Each package needs all four chemicals in it to hold everything in solution. They differ in how much of each they contain. If blood serum is spun very rapidly in an ultracentrifuge, these five packages will layer out according to their density. They have been named according to their densities—high-density lipoproteins (HDL), low-density lipoproteins (LDL), intermediate-density lipoproteins (IDL), very **low density lipoproteins** (VLDL), and chylomicrons.

If there is not enough detergent in the laundry, the oily stains will remain in the clothes. In the same way, if the balance of chemicals in these packages is not right, cholesterol will stay in tissues rather than being excreted from the body. What is even worse, if the chemical composition of these packages changes, the cholesterol can fall out of the blood and stay where it lands. On the other hand, a different change in the balance can remove cholesterol from tissues where there is too much. This appears to be exactly what is going on in atherosclerosis. The lesions contain lots of cholesterol.

The LDLs are overloaded with cholesterol. A minor change in the other chemicals in this package will leave cholesterol behind. The HDLs have a third to a half as much cholesterol. They seem to be able to pick up cholesterol left behind by the LDLs. Atherosclerosis begins with tiny tears at stressed places in the walls of the arteries. LDLs from the blood enter these tears, where their chemistry changes enough to leave cholesterol behind. The cholesterol causes irritation; the body responds with inflammation; damage and scarring follow. Eventually, the artery gets so diseased blood cannot flow through it. Strokes and heart attacks are the result.

However, if there are lots of HDLs in the blood, the cholesterol is rapidly picked up and not allowed to cause problems. Women before **menopause** have estrogen (the female hormone), which encourages the formation of HDLs. This is the reason they have so little vascular disease and why they rapidly catch up to men after menopause, when estrogen levels fall. Replacement of estrogen after menopause has been prescribed for protection through the later years. However, in 2003, the Women's Health Initiative, a large clinical trial involving postmenopausal women, was halted in July 2002 because of the many detrimental effects of combined estrogen and progesterone therapy (called **hormone replacement therapy**). Among the effects was increased risk of **heart disease**, sometimes within the first year of use.

WWW.BOOKBAZ.IR

Cholesterol is the root of the problem, but like any other root it cannot just be eliminated. Ninety percent of the cholesterol in the body is created there as a waste product of necessary processes. The solution lies in getting it out to the body without clogging the arteries.

The body has dozens of chemical processes that make up, break down, and reconfigure all these chemicals. It is these processes that are the targets of intervention in the effort to cure vascular disease.

Diseases

Near the dawn of concern over cholesterol and vascular disease a family of hereditary diseases was identified, all of which produced abnormal quantities of blood fats. These diseases were called dyslipoproteinemias and came in both too many and too little varieties. The hyperlipoproteinemias found their way into five categories, depending on which chemical was in excess.

- Type 1 has a pure elevation of triglycerides in the chylomicron fraction. These people sometimes get pancreatitis and abdominal pains, but they do not seem to have an increase in vascular disease.
- Type 2 appears in two distinct genetic patterns and a third category, which is by far the most important kind, because everyone is at risk for it. All Type 2s have elevated cholesterol. Some have elevated triglycerides also. The familial (genetic) versions of Type 2 often develop xanthomas, which are yellow fatty deposits under the skin of the knuckles, elbows, buttocks or heels. They also may have xanthelasmas, smaller yellow patches on the eyelids.
- Type 3 appears in one in 10,000 people and elevates both triglycerides and cholesterol with consequent vascular disease. In 2003, researchers discovered the molecular mechanism that contributes to high triglycerides in those with this type of hyperlipopoproteinemia.
- Type 4 elevates only triglycerides and does not increase the risk of vascular disease.
- Type 5 is similar to Type 1.
- Dyslipidemia refers to a normal amount of cholesterol that is mostly in LDLs, where it causes problems.

All but Type 2 are rare and of interest primarily because they give insight into the chemistry of blood fats.

In addition to the genetic causes of blood fat disorders, a number of acquired conditions can raise lipoprotein levels:

- Diabetes mellitus, because it alters the way the body handles its energy needs, and also affects the way it handles fats. The result is elevated triglycerides and reduced HDL cholesterol. This effect is amplified by obesity.
- Hypothyroidism is a common cause of lipid abnormalities. The thyroid hormone affects the rate of many chemical processes in the body, including the clearing of fats from the blood. The consequence usually is an elevation of cholesterol.
- Kidney disease affects the blood's proteins and consequently the composition of the fat packages. It usually raises the LDLs.
- Liver disease, depending on its stage and severity, can raise or lower any of the blood fats.
- Alcohol raises triglycerides. In moderate amounts (if they are very moderate) it raises HDLs and can be beneficial.
- Cigarette smoking lowers HDL cholesterol, as does malnutrition and obesity.

Certain medications elevate blood fat levels. Because some of these medications are used to treat heart disease, it has been necessary to reevaluate their usefulness:

- Thiazides, water pills used to treat high blood pressure, can raise both cholesterol and triglycerides.
- Beta-blockers, another class of medication used to treat high blood pressure, cortisone-like drugs, and estrogen can raise triglycerides.
- Progesterone, the pregnancy hormone, raises cholesterol.

Not all of these effects are necessarily bad, nor are they necessarily even significant. For instance, estrogen is clearly beneficial. Each effect must be considered in the overall goal of treatment.

Causes and symptoms

A combination of heredity and diet is responsible for the majority of fat disorders. It is not so much the cholesterol in the diet that is the problem, because that accounts for only 10% of the body's store. It is the other fats in the diet that alter the way the body handles its cholesterol. There is a convincing relation between fats in the diet and the incidence of atherosclerosis. The guilty fats are mostly the animal fats, but palm and coconut oil also are harmful. These fats are called saturated fats for the chemical reason that most of their carbon atoms have as many hydrogen atoms attached as they can accommodate. More important than the kind of fat is the amount of fat. For many people, fat is half of their diet. One-fifth to one-fourth

is a much healthier fraction, the rest of the diet being made up of complex carbohydrates and protein.

This disease is silent for decades, until the first episode of heart disease or **stroke**.

Diagnosis

It would be easier if simple **cholesterol and triglyceride tests** were all it took to assess the risk of atherosclerosis. However, the important information is which package the cholesterol is in—the LDLs or the HDLs. That takes a more elaborate testing process. To complicate matters further, the amount of fats in the blood varies greatly in relation to the last meal—how long ago it was and what kind of food was eaten. A true estimate of the risk comes from several tests several weeks apart, each done after at least 12 hours of **fasting**.

Treatment

Diet and lifestyle change are the primary focus for most cholesterol problems. It is a mistake to think that a pill will reverse the effects of a bad diet, **obesity**, **smoking**, excess alcohol, **stress**, and inactivity. Reducing the amount of fat in the diet by at least half is the most important move to make. Much of the food eaten to satisfy a "sweet tooth" is higher in fat than in sugar. A switch away from saturated fats is the next step, but the rush to polyunsaturated fats was ill-conceived. These, particularly the hydrogenated fats in margarine, have problems of their own. They raise the risk of cancer and are considered more dangerous than animal fat by many experts. Theory supports population studies that suggest monounsaturated olive oil may be the healthiest of all.

There was a tremendous push at the end of the 20th century to use lipid-lowering medications. The most popular and most expensive agents, the "statins," hinder the body's production of cholesterol and sometimes damage the liver as a side effect. Their full name is 3-hydroxy-3-methylglutaryl-coemzyme A *(HMG-CoA)* reductase inhibitors. Their generic names are cervistatin, fluvastatin, lovastatin, pravastatin, simvastatin, and rosuvastatin. Studies show that these drugs lower cholesterol. Only recently, though, has any evidence appeared that this affects health and longevity. Earlier studies showed, in fact, an increased death rate among users of the first class of lipid-altering agents—the fibric acid derivatives. The chain of events connecting raised HDL and lowered LDL cholesterol to longer, healthier lives is still to be forged.

High-tech methods of rapidly reducing very high blood fat levels are performed for those rare disorders that require it. There are resins that bind cholesterol in the intestines. They taste awful, feel like glue and routinely cause gas, bloating, and **constipation**. For acute cases, there is a filtering system that takes fats directly out of the blood.

Niacin (nicotinic acid) lowers cholesterol effectively and was the first medication proven to improve overall life expectancy. It also can be liver toxic, and the usual formulation causes a hot flash in many people. This can be overcome by taking a couple of aspirins 30 minutes before the niacin, or by taking a special preparation called "flush free," "inositol-bound" or inositol hexanicotinate.

Alternatives

Omega-3 oil is found mostly in certain kinds of fish. It is beneficial in lowering cholesterol. An herbal alternative called guggulipid, *Commiphora mukul*, an extract of an Indian plant, has been touted as working the same way as the expensive and liver toxic cholesterol-lowering medications. However, a 2003 clinical trial found that the supplement did not meet these claims. In fact, guggul did not lower total cholesterol, LDL cholesterol, or triglycerides. Most patients tolerated the supplement, but some developed a hypersensitivity rash.

To lower cholesterol, **naturopathic medicine**, **traditional Chinese medicine**, and **ayurvedic medicine** may be considered. Some herbal therapies include alfalfa (*Medicago sativa*), Asian **ginseng** (*Panax ginseng*), and fenugreek (*Trigonella foenum-graecum*). Garlic (*Allium sativum*) and onions are also reported to have cholesterol-lowering effects. In naturopathic medicine, the liver is considered to be an organ that needs cleansing and rebalancing. The liver often is treated with a botanical formula that will act as a bitter to stimulate bile flow in the liver. Before initiating alternative therapies, medical consultation is strongly advised.

Prognosis

The prognosis is good for Type 1 hyperlipoproteinemia with treatment; without treatment, death may result. For Type 2 the prognosis is poor even with treatment. The prognosis for Type 3 is good when the prescribed diet is strictly followed. For Types 4 and 5 the prognosis is uncertain, due to the risk of developing premature **coronary artery disease** and **pancreatitis**, respectively.

WWW.BOOKBAZ.IR

Prevention

Genetic inheritance cannot be changed, but its effects may be modified with proper treatment. Family members of an individual with hyperlipoproteinemia should consider having their blood lipids assessed. The sooner any problems are identified, the better the chances of limiting or preventing the associated health risks. Anyone with a family history of disorders leading to hyperlipoproteinemia also may benefit from **genetic testing** and counseling to assist them in making reproductive decisions.

Hypernatremia

Definition

The normal concentration of **sodium** in the blood plasma is 136–145 mEq/L. Hypernatremia is defined as a serum sodium level over 145 mEq/L. Severe hypernatremia, with serum sodium above 152 mEq/L, is a rare disorder in patients with an intact thirst response that can result in seizures and death if left untreated.

Description

Sodium is an atom, or ion, that carries a single positive charge. The sodium ion may be abbreviated as Na^+ or as simply Na. Sodium can occur as a salt in a crystalline solid. Sodium chloride (NaCl), sodium phosphate (Na_2HPO_4) and sodium bicarbonate ($NaHCO_3$) are commonly occurring salts. These salts can be dissolved in water or in juices of various foods. Dissolving involves the complete separation of ions, such as sodium and chloride, in common table salt (NaCl).

About 40% of the body's sodium is contained in bone. Approximately 2–5% occurs within organs and cells and the remaining 55% is in blood plasma and other extracellular fluids. The amount of sodium in blood plasma is typically 140 mEq/L, a much higher amount than is found in intracellular sodium (about 5 mEq/L). This asymmetric distribution of sodium ions is essential for human life. It makes possible proper nerve conduction, the passage of various nutrients into cells, and the maintenance of blood pressure.

The body continually regulates its handling of sodium. When dietary sodium is too high or low, the intestines and kidneys respond to adjust concentrations to normal. During the course of a day, the intestines absorb dietary sodium while the kidneys excrete a nearly equal amount of sodium into the urine. If a low sodium diet is consumed, the intestines increase their efficiency of sodium absorption, and the kidneys reduce its release into urine.

The concentration of sodium in the blood plasma depends on two things: the total amount of sodium and water in arteries, veins, and capillaries (the circulatory system). The body uses separate mechanisms to regulate sodium and water, but they work together to correct blood pressure when it is too high or too low. Too high a concentration of sodium, or hypernatremia, can be corrected either by decreasing sodium or by increasing body water. The existence of separate mechanisms that regulate sodium concentration account for the fact that there are numerous diseases that can cause hypernatremia, including diseases of the kidney, pituitary gland, and hypothalamus.

Causes and symptoms

Vasopressin, also called anti-diuretic hormone, is made by the hypothalamus and released by the pituitary gland into the bloodstream. There it travels to the kidney where it reduces the release of water into the urine. With less vasopressin production, the body fails to conserve water, and the result is a trend toward higher plasma sodium concentrations. Hypernatremia

may occur in **diabetes insipidus**, a disease that causes excessive urine production. (It is not the same disease as **diabetes mellitus**, a disease resulting from impaired insulin production.) The defect involves either the failure of the hypothalamus to make vasopressin or the failure of the kidney to respond to vasopressin. In either case, the kidney is able to conserve and regulate the body's sodium levels, but is unable to conserve and retain the body's water. Hypernatremia does not occur in diabetes insipidus if the patient is able to drink enough water to keep up with urinary loss, which may be as high as 10 L per day.

Hypernatremia may occur in unconscious (or comatose) patients due to the inability to drink water. Water is continually lost by evaporation from the lungs and in the urine. If the patient is not given water via infusion, the sodium concentration in the blood may increase and hypernatremia could develop.

Hypernatremia can occur in individuals in which the thirst impulse is impaired or who cannot satisfy the thirst impulse on their own. Hypernatremia induced by these mechanisms is most likely to occur in infants, in psychiatric patients, and in elderly patients, especially those confined to institutionalized care settings.

Hypernatremia can occur accidentally in the hospital when patients are infused with solutions containing sodium, such as sodium bicarbonate for the treatment of acidosis (acidic blood). It can also be accidentally induced with sodium chloride infusions, especially in elderly patients with impaired kidney function.

Hypernatremia can cause neurological damage due to shrinkage of brain cells. Neurological symptoms include confusion, **coma**, **paralysis** of the lung muscles, and death. The severity of the symptoms is related to how rapidly the hypernatremia developed. Hypernatremia that comes on rapidly does not allow the cells of the brain time to adapt to their new high-sodium environment. Hypernatremia is especially dangerous for children and the elderly.

Diagnosis

Tests

Hypernatremia is diagnosed by acquiring a blood sample and then measuring the concentration of sodium ions in the blood. Other tests that may be ordered in the diagnosis of hypernatremia include urine osmolality, urine sodium, and serum glucose tests. A head CT scan or **magnetic resonance imaging** test (MRI) may be ordered in patients with severe hypernatremia. Less frequently ordered tests that may be utilized include a water deprivation test and an antidiuretic hormone (ADH) simulation test.

KEY TERMS

Acidosis—A medical condition caused by an increase in the concentration of hydrogen ions in the blood. The result of this increase is a lowered (acidic) blood pH level.

mEq/L—Abbreviation for milliequivalents per liter. Some medical tests results are reported in mEq/L.

Plasma—Clear, yellow- or straw-colored fluid that is the liquid component of blood and lymphatic fluid.

Treatment

Hypernatremia is treated with infusions of a solution of water containing 0.9% sodium chloride (0.9 g NaCl/100 mL water), which is the normal concentration of sodium chloride in the blood plasma. The infusion is performed over many hours or days to prevent abrupt and dangerous changes in brain cell volume. When possible, patients should be encouraged to drink water unless contraindicated for other medical reasons. In emergencies, such as when hypernatremia is causing neurological symptoms, infusions may be conducted with salt solutions containing 0.45% sodium chloride, which is half the normal physiologic level.

Prognosis

The prognosis for treating hypernatremia is excellent, except if neurological symptoms are severe or if overly rapid attempts are made to treat and reverse the condition. Some patients may be left with permanent neurological damage despite treatment.

Prevention

Hypernatremia occurs only in unusual circumstances that are not normally under a person's control. Monitoring the fluid consumption of vulnerable individuals, particularly those in institutionalized care settings, is strongly recommended. As hypernatremia in infants is most often caused by not receiving enough breast milk from the mother or from inaccurate

WWW.BOOKBAZ.IR

formula preparation, educating new parents to these possibilities is important before the infant leaves the hospital.

Hyperopia

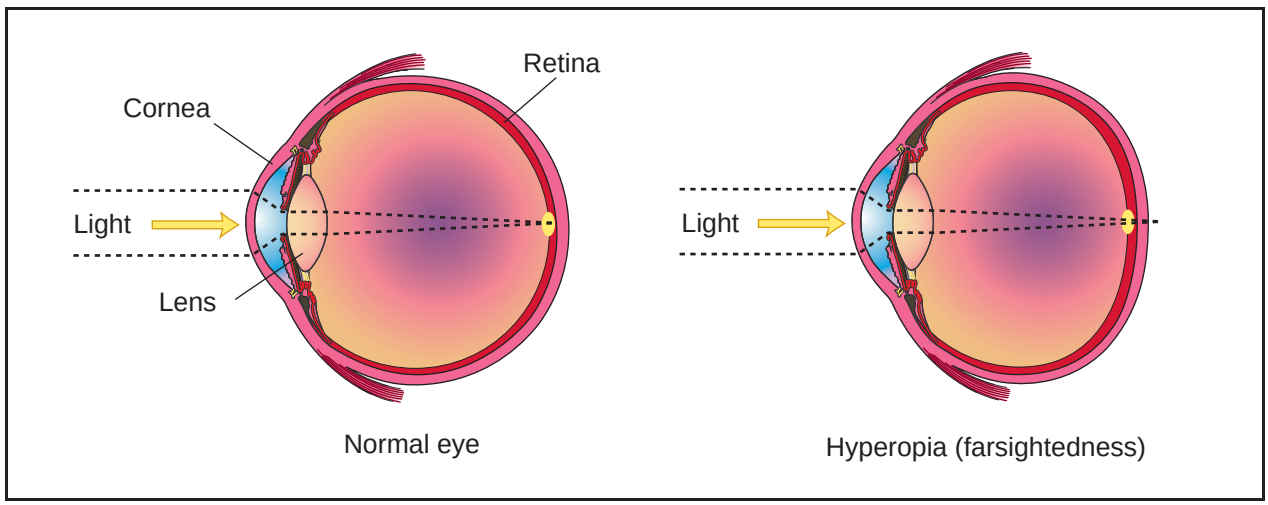
Definition

Hyperopia (farsightedness) is the condition of the eye where incoming rays of light reach the retina before they converge into a focused image.

Description

When light goes through transparent but dense material like the materials of the eye's lens system (the lens and cornea), its velocity decreases. If the surface of the dense material is not perpendicular to the incoming light, as is the case with the curved surfaces on lenses and corneas, the direction of the light changes. The greater the curvature of the lens system, the greater the change in the direction of the light.

When parallel light rays from an object go through the lens system of the eye, they are bent so they converge at a point some distance behind the lens. With perfect vision this point of convergence, where the light rays are focused, is on the retina. This happens when the cumulative curvature of the lens plus cornea and the distance from the lens to the retina are just right for each other. The condition where the point of focus of parallel light rays from an object is behind the retina is called hyperopia. This condition exists when the combined curvature of the lens and cornea is insufficient (e.g., flatter than needed for the length of the eyeball). This condition can be equivalently described by saying hyperopia exists when the eyeball is too short for the curvature of its lens system.



Hyperopia, or farsightedness, is a condition of the eye where incoming rays of light impinge on the retina before converging into a focused image, resulting in difficulty seeing nearby objects clearly. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

There is a connection between the focusing of the lens of the eye (accommodation) and convergence of the eyes (the two eyes turning in to point at a close object). The best example is during reading. The lens accommodates to make the close-up material clear and the eyes turn in to look at the print and keep it single. Because of this connection between accommodation and convergence, if the lens needs to accommodate to focus for distance (to bring the image back onto the retina) the eyes may appear to turn in even when looking at the distance. This can cause a condition known as accommodative esotropia in children. The eyes turn in and the cause is accommodation because of hyperopia.

Causes and symptoms

Babies are generally born slightly hyperopic. This tends to decrease with age. There is normal variation in eyeball length and curvature of the lens and cornea. Some combinations of these variables give rise to eyes where the cornea is too flat for the distance between the cornea and the retina. If the hyperopia is not too severe the lens may be able to accommodate and bring the image back onto the retina. This would result in clear distance vision, but the constant focusing might result in headaches or eyestrain. If the lens cannot accommodate for the full amount of the hyperopia the distance image would be blurry.

If the eyes are focusing for distance and now the person is looking at a near object, the eyes need to accommodate further. This may result in blurry near by objects or headaches during close work.

Depending upon the amount of hyperopia, symptoms can range from none to clear distance vision but blurry near vision, to blurry distance and near vision. Headaches and eyestrain may also occur, particularly when doing near tasks. An eye turned in (esotropia) may be a result of hyperopia, particularly in children. However, because a turned eye may be a result of more serious causes it is very important to have it checked out.

Diagnosis

Because it is possible to have good visual acuity with some degree of hyperopia, it is important to relax accommodation before the eye exam. This is done with the use of eyedrops and is called a cycloplegic exam or cycloplegic refraction. The drops relax the accommodation (making reading blurry until the drops wear off). Patients will usually be asked to have someone drive them home because of the blurriness. The doctor can then determine the patient's visual status with a handheld instrument called a retinoscope and/or have the patient read from an eye chart while placing different lenses in front of the patient's eyes. Refractive error is measured in units called diopters (D).

Treatment

The usual treatment for hyperopia is corrective lenses (spectacles or **contact lenses**).

Different surgical methods to correct hyperopia are under investigation. One approach is to implant corrective contact lenses behind the patient's iris. The first experimental implantable contact lenses were implanted in 1997. Another approach is to surgically increase the curvature of the eye's existing cornea or lens. Although there have been many reports of success using different kinds of lasers to increase corneal curvature, there are still problems with stability and predictability. The introduction of light-activated biologic tissue glue in 1997 holds promise for improvements in those areas.

Prognosis

The prognosis for fully corrected vision is excellent for patients with low to moderate amounts of hyperopia. Patients with very high hyperopia (+10.00D or more) may not achieve full correction. Surgery to correct hyperopia may be perfected and approved in the near future.

Hyperopia increases the chances of chronic **glaucoma**, but vision loss from glaucoma is preventable.

Prevention

Hyperopia is usually present at birth, and there is no known way to prevent it.

Hyperparathyroidism

Definition

Parathyroid glands are four pea-sized glands located just behind the thyroid gland in the front of the neck. The function of parathyroid glands is to

WWW.BOOKBAZ.IR

produce a hormone called parathyroid hormone (parathormone), which helps regulate **calcium** and phosphate in the body. Hyperparathyroidism is the overproduction of this hormone.

Description

Thyroid glands and parathyroid glands, despite their similar name and proximity, are entirely separate, and each produces hormones with different functions. Hyperparathyroidism may be primary or secondary. It most often occurs in those over age 30, and most commonly in patients 50–60 years old. It rarely occurs in children or the elderly. Women are affected by the disease up to three times more often than men. It is estimated that 28 of every 100,000 people in the United States will develop hyperparathyroidism each year.

Normally, parathyroid glands produce the parathormone as calcium levels drop and lower to meet the demands of a growing skeleton, **pregnancy**, or **lactation**. However, when one or more parathyroid glands malfunctions, it can lead to overproduction of the hormone and elevated calcium level in the blood. Therefore, a common result of hyperparathyroidism is **hypercalcemia**, or an abnormally high level of calcium in the blood. Primary hyperparathyroidism occurs as a malfunction of one of the glands, usually as a result of a benign tumor called an adenoma. Secondary hyperparathyroidism occurs as the result of a metabolic abnormality outside the parathyroid glands, which causes a resistance to the function of the parathyroid hormones. Primary hyperparathyroidism is one of the most common endocrine disorders, led only by diabetes and **hyperthyroidism**.

Causes and symptoms

Often, there are no obvious symptoms or suspicion of hyperparathyroidism, and it is first diagnosed when a patient is discovered to be hypercalcemic during a routine blood chemistry profile. Patients may believe they have felt fine, but realize improvements in sleep, irritability, and memory following treatment. When symptoms are present, they may include development of gastric **ulcers** or **pancreatitis** because high calcium levels can cause inflammation and **pain** in the linings of the stomach and pancreas.

Most of the symptoms of hyperparathyroidism are those present as a result of hypercalcemia, such as **kidney stones**, **osteoporosis**, or bone degradation resulting from the bones giving up calcium. Muscle weakness, central nervous system disturbances such as depression, psychomotor and personality disturbances, and rarely, even **coma** can occur. Patients may also experience **heartburn**, nausea, **constipation**, or abdominal pain. In secondary hyperparathyroidism, patients may show signs of calcium imbalance such as deformities of the long bones. Symptoms of the underlying disease may also be present.

Most commonly, hyperparathyroidism occurs as the result of a single adenoma, or benign tumor, in one of the parathyroid glands. About 90% of all cases of hyperparathyroidism are caused by an adenoma. The tumors are seldom cancerous. They will grow to a much larger size than the parathyroid glands, often to the size of a walnut. Genetic disorders or multiple endocrine tumors can also cause a parathyroid gland to enlarge and oversecrete hormone. In 10% or fewer of patients with primary hyperparathyroidism, there is enlargement of all four parathyroid glands. This condition is called parathyroid hyperplasia.

Diagnosis

Diagnosis of hyperparathyroidism is most often made when a blood test (radioimmunoassay) reveals high levels of parathyroid hormone and calcium. A blood test that specifically measures the amount of parathyroid hormone has made diagnosis simpler. X ray examinations may be performed to look for areas of diffuse bone demineralization, bone cysts, outer bone absorption and erosion of the long bones of the fingers and toes. Hypercalcemia is mild or intermittent in some patients, but is an excellent indicator of primary hyperparathyroidism. Dual energy x ray absorptiometry (DEXA or DXA), a tool used to diagnose and measure osteoporosis, is used to show reduction in bone mass for primary hyperparathryroidism patients. Once a diagnosis of hyperparathyroidism is reached, the physician will probably order further tests to evaluate complications. For example, abdominal radiographs might reveal kidney stones.

For secondary hyperparathyroidism, normal or slightly decreased calcium levels in the blood and variable phosphorous levels may be visible. Patient history of familial **kidney disease** or convulsive disorders may suggest a diagnosis of secondary hyperparathyroidism. Other tests may reveal a disease or disorder, which is causing the secondary hyperparathyroidism.

Treatment

Hyperparathyroidism cases will usually be referred to an endocrinologist, a physician specializing in hormonal problems, or a nephrologist, who specializes in kidney and mineral disorders.

Patients with mild cases of hyperparathyroidism may not need immediate treatment if they have only slight elevations in blood calcium level and normal kidneys and bones. These patients should be regularly checked, probably as often as every six months, by **physical examination** and measurement of kidney function and calcium levels. A bone densitometry measurement should be performed every one or two years. After several years with no worsened symptoms, the length of time between exams may be increased.

Patients with more advanced hyperparathyroidism will usually have all or half of the affected parathyroid gland or glands surgically removed. This surgery is relatively safe and effective. The primary risks are those associated with general **anesthesia**. There are some instances when the surgery can be performed with the patient under regional, or cervical block, anesthesia. Often studies such as ultrasonography prior to surgery help pinpoint the affected areas.

Alternatives

Forcing fluids and reducing intake of calcium-rich foods can help decrease calcium levels prior to surgery or if surgery is not necessary.

Prognosis

Removal of the enlarged parathyroid gland or glands cures the disease 95% of the time and relief of bone pain may occur in as few as three days. In up to 5% of patients undergoing surgery, chronically low calcium levels may result, and these patients will require a calcium supplement or **vitamin D** treatment. Damage to the kidneys as a result of hyperparathyroidism is often irreversible. Prognosis is generally good; however, complications of hyperparathyroidism such as osteoporosis, bone **fractures**, kidney stones, peptic ulcers, pancreatitis, and nervous system difficulties may worsen the prognosis.

Prevention

Secondary hyperparathyroidism may be prevented by early treatment of the disease causing it. Early recognition and treatment of hyperparathyroidism may prevent hypercalcemia. Since the cause of primary hyperparathyroidism, or the adenoma that causes parathyroid enlargement, is largely unknown, there are no prescribed prevention methods.

Hyperpigmentation

Definition

Hyperpigmentation is the increase in the natural color of the skin.

Description

Melanin, a brown pigment manufactured by certain cells in the skin called melanocytes, is responsible for skin color. Melanin production is stimulated by a pituitary hormone called melanocyte stimulating hormone (MSH). Other pigments appear in the skin much less often.

Causes and symptoms

Darkened spots on the skin come in several varieties. The most ominous is malignant **melanoma**, a very aggressive cancer that begins as an innocent mole. The majority of **moles** (nevus) are and remain benign (harmless). The average person has several dozen, and certain people with a hereditary excess may have hundreds. Freckles, age spots, and cafe au lait spots, known as ephelides, are always flat and not as dark. Cafe au lait spots are seen mostly in people with another hereditary disorder called **neurofibromatosis**. "Port wine stains" are congenital dark red blotches on the skin. Other common dark colorations on the skin are called keratosis and consist of locally overgrown layers of skin that are dark primarily because there is more tissue than normal. A few of these turn into skin cancers of a much less dangerous kind than melanoma.

Darkened regions of the skin occur as a result of abnormal **tanning** when the skin is sensitive to sunlight. Several diseases and many drugs can cause **photosensitivity**. Among the common drugs responsible for this uncommon reaction are birth control pills, **antibiotics** (**sulfonamides** and **tetracyclines**), **diuretics**, **nonsteroidal anti-inflammatory drugs** (NSAID), **pain** relievers,

WWW.BOOKBAZ.IR

and some psychoactive medications. Some of the same drugs may also cause patches of discolored skin known as localized drug reactions and representing an allergy to that drug. Sunlight darkens an abnormal chemical in the skin of patients with porphyria cutanea tarda. Several endocrine diseases, some cancers, and several drugs abnormally stimulate melanocytes, usually through an overproduction of MSH. Arsenic **poisoning** and Addison's disease are among these causes. A condition known as acanthosis nigricans is a velvety darkening of skin in folded areas (arm pits, groin, and neck) that can signal a cancer or hormone imbalance.

Of particular note is a condition called melasma (dark pigmentation of the skin), caused by the female hormone estrogen. Normal in **pregnancy**, this brownish discoloration of the face can also happen with birth control pills that contain estrogen.

Overall darkening of the skin may be due to pigmented chemicals in the skin. Silver, gold, and iron each have a characteristic color when visible in the skin. Several drugs and body chemicals, like bilirubin, can end up as deposits in the skin and discolor it.

There are a number of other rare entities that color the skin, each in its own peculiar way. Among these are strange syndromes that seem to be **birth defects** and vitamin and nutritional deficiencies.

Diagnosis

The pattern of discoloration is immediately visible to the trained dermatologist, a physician specializing in skin diseases, and may be all that is required to name and characterize the discoloration. Many of these pigment changes are signs of internal disease that must be identified. Pigmentation changes may also be caused by medication, and the drug responsible for the reaction must be identified and removed.

Treatment

Skin sensitive to sunlight must be protected by shade or **sunscreens** with an SPF of 15 or greater. Skin cancers must be, and unsightly benign lesions may be, surgically removed. **Laser surgery** is an effective removal technique for many localized lesions. Because it spreads so rapidly, melanoma should be immediately removed, as well as some of the surrounding tissue to prevent regrowth.

Prevention

Sunlight is the leading cause of dark spots on the skin, so shade and sunscreens are necessary preventive strategies, especially in people who burn easily.

Hypersensitivity pneumonitis

Definition

Hypersensitivity pneumonitis refers to an inflammation of the lungs caused by repeated breathing in of a foreign substance, such an organic dust, a fungus, or a mold. The body's immune system reacts to these substances, called antigens, by forming antibodies, molecules that attack the invading antigen and try to destroy it. The combination of antigen and antibody produces acute inflammation, or pneumonitis (a hypersensitivity reaction), which later can develop into chronic lung disease that impairs the lungs' ability to take oxygen from the air and eliminate carbon dioxide.

Description

Hypersensitivity pneumonitis (HP) is sometimes called allergic alveolitis. "Allergic" refers to the antigen-antibody reaction, and "alveolitis" means an inflammation of the tiny air sacs in the lungs where oxygen and CO_2 are exchanged, the alveoli. It also is known as extrinsic allergic alveolitis, meaning that the antigen that sets up the allergic reaction (also called an allergen) comes from the outside. Most of the antigens that cause this disease come from plant or animal proteins or microorganisms, and many of those affected are exposed either at work or in the course of some hobby or other activity. The first known type of HP, farmer's lung, is caused by antigens from tiny microorganisms living on moldy hay. An example of disease connected with a hobby is pigeon breeder's lung, caused by inhaling protein material from bird droppings or feathers. After a time, very little of the allergenic material is needed to set off a reaction in the lungs.

Roughly one in every 10,000 persons develops some form of HP. A mysterious aspect of this condition is that, even though many persons may be exposed to a particular antigen, only a small number

of them will develop the disease. Genetic differences may determine who becomes ill; this remains unclear. Probably between 5% and 15% of all persons who are regularly exposed to organic materials develop HP. Most of those who do get it do *not* smoke (**smoking** may create the type of cells that take up antigens and neutralize them). The amount of antigen is an important factor in whether HP will develop and what form it will take. Sudden heavy exposure can produce symptoms in a matter of hours, whereas mild but frequent exposures tend to produce a long-lasting, "smoldering" illness. HP may be more likely to develop in persons exposed to polluted air or industrial fumes.

Typical changes occur in the lungs of persons with HP. In the acute stage, large numbers of inflammatory cells are found throughout the lungs and the air sacs may be filled by a thick fluid mixed with these cells. In the subacute stage, disease extends into the small breathing tubes, or bronchioles, and the inflammatory cells collect into tiny granules called granulomas. Finally, in the chronic stage of HP, the previously inflamed parts of the lungs become scarred and unable to function, as in **pulmonary fibrosis**.

Causes and symptoms

A number of different types of HP are known, since a wide range of allergens may produce an allergic reaction in the lungs. Many of them produce similar symptoms and abnormal physical findings, but some have their own typical features. Some of the more common forms are:

- Farmer's lung. This can affect any farmer who works with wet hay or other moldy dust. Small farmers who have to directly thresh and handle their hay are most at risk, as are those living in cold and humid areas where damp weather is common.
- Pigeon breeder's lung. Also called bird fancier's lung, it is second to farmer's lung as the best known type of HP. A substance has been found in pigeon droppings that may cause the allergic reaction, but there may be more than one such substance. Besides pigeons, the disorder may follow exposure to ducks, geese, pheasants, and even canaries. Parakeets produce an especially severe form of disease. Most patients are middle-aged women, who usually care for birds either at home or on bird breeding farms.
- Bagassosis. Caused by bagasse, a substance produced when juice is extracted from sugar cane and is used in making paper and explosives. A fungus is probably responsible. Young and middle-aged men who work in the sugar industry are at risk.
- Byssinosis. A similar condition affecting workers who inhale dust from cotton, flax, or hemp.
- Humidifier lung. An acute form of HP caused by inhaling actinomycetes, the same organisms that cause farmer's lung, which grow in contaminated humidifier vents, air conditioners, heating systems, and even saunas.
- Other antigens. HP has been seen in persons working with detergents, silicone, mushrooms, cheese, wood dust, maple bark, coffee, and furs.

In the acute stage, patients with HP begin coughing, develop **fever**, and note tightness in the chest as well as extreme tiredness and aching, 4–8 hours after the most recent exposure. Most patients are well aware of the connection between their work (or an activity) and their symptoms. After a time, patients may have trouble breathing. They also may lose their appetite, lose weight, and generally feel ill. Finally, in the chronic stage, the patient will have increasing trouble breathing and may sometimes wheeze. With advanced disease, the skin may appear bluish (because too little oxygen is getting into the blood). When a physician listens to the patient's chest with a stethoscope, there may be crackling sounds or loud **wheezing**. In the late stages, club-shaped fingertips are a sign that the patient has not been getting enough oxygen for an extended period of time.

Diagnosis

No single test can make a definite diagnosis of HP. The key is to relate some specific exposure or activity to episodes of symptoms. A chest x ray may be normal in the acute stage, but later may show a hazy appearance that looks like ground glass. There may be linear or rounded shadows in the central parts of the lungs. Studies of lung function in the acute stage typically show abnormally small lung volume. The ability to breathe at a fast rate is impaired. Blood from an artery typically has a low level of oxygen. Later, when the lungs have begun to scar, the airways (breathing tubes) are obstructed and the rate of air flow is reduced.

Some experts believe that skin testing can help diagnose HP and show which particular antigen is causing the symptoms. Small amounts of several suspect antigens are injected just beneath the surface of the skin, usually on the arm or back, and the reactions compared to that caused by injecting a harmless salt solution. Another diagnostic test is to place a thin tube into the airways, inject a small amount of fluid, and draw it back up (bronchoalveolar lavage). A very large

WWW.BOOKBAZ.IR

number of cells called lymphocytes is typical of HP, and mast cells, which are part of the immune system, may also be seen. Rarely, a tissue sample (biopsy) of lung tissue may be taken through a tube placed in the airways and examined under a microscope. Finally, a patient may be "challenged" by actually inhaling a particular antigen in the form of an aerosol and noting whether lung function suddenly becomes worse. This test is usually not necessary.

Treatment

Treatment of HP requires identifying the offending antigen and avoiding further exposure. Although it may sometimes be necessary for a patient to find a totally different type of work, often it is possible to simply perform different duties or switch to a work site where exposure is minimal. In some cases, (like pigeon breeder's lung), wearing a mask can prevent exposure. If acute symptoms are severe, the patient may be treated with a steroid hormone for two to six weeks. This often suppresses the inflammatory response and allows the lungs a chance to recover. In the chronic stage, steroid treatment can delay further damage to the lungs and help preserve their function.

Prognosis

In general, most of the symptoms of HP disappear when the patient is no longer exposed to the causative allergen. The actual chances of complete recovery depend in part on what form of HP is present. Older patients and those exposed repeatedly for long periods after initially developing symptoms tend to have a poorer long-term outlook. The worst outcome is that long repeated episodes of exposure will cause chronic lung inflammation, scar the lungs, and permanently make then unable to properly provide oxygen to the blood. Rarely, a patient will become permanently disabled.

Prevention

It is often not possible to prevent initial episodes of HP because there is no way of predicting which individuals (such as farmers) will have an allergic reaction to a particular allergen. Once the connection is made between a type of exposure and definite hypersensitivity symptoms, prevention of further episodes is simple as long as further exposure can be avoided.

Exactly how to avoid exposure depends on a person's work or activities and what is causing the reaction. People with farmer's lung can dry hay thoroughly before storing it. For pigeon breeder's lung (and many other types of HP), a mask can be worn. In many industrial settings, it is possible to take precautions that will limit the amount of allergen that workers will inhale. If it is not possible to avoid exposure altogether, exposure can be timed and strictly minimized.

Hypersomnia *see* **Sleep disorders**

Hypersplenism

Definition

Hypersplenism is a type of disorder that causes the spleen to rapidly and prematurely destroy blood cells.

Description

The spleen is located in the upper left area of the abdomen. One of this organ's major functions is to remove blood cells from the body's bloodstream. In hypersplenism, its normal function accelerates, and it begins to automatically remove cells that may still be normal in function. Sometimes the spleen will temporarily hold onto up to 90% of the body's platelets and 45% of the red blood cells. Hypersplenism may occur as a primary disease, leading to other complications, or as a secondary disease, resulting from an underlying disease or disorder. Hypersplenism is sometimes referred to as enlarged spleen (splenomegaly). An enlarged spleen is one of the symptoms of hypersplenism. What differentiates hypersplenism is its premature destruction of blood cells.

Causes and symptoms

Hypersplenism may be caused by a variety of disorders. Sometimes, it is brought on by a problem within the spleen itself and is referred to as primary hypersplenism. Secondary hypersplenism results from another disease such as chronic **malaria**, **rheumatoid arthritis**, **tuberculosis**, or **polycythemia vera**, a blood

disorder. Spleen disorders in general are almost always secondary in nature. Hypersplenism may also be caused by tumors.

Symptoms of hypersplenism include easy bruising, easy contracting of bacterial diseases, **fever**, weakness, heart **palpitations**, and ulcerations of the mouth, legs, and feet. Individuals may also bleed unexpectedly and heavily from the nose or other mucous membranes and from the gastrointestinal or urinary tracts. Most patients will develop an enlarged spleen, anemia, leukopenia, or abnormally low white blood cell counts, or **thrombocytopenia**, a deficiency of circulating platelets in the blood. Other symptoms may be present that reflect the underlying disease that has caused hypersplenism.

An enlarged spleen can be caused by a variety of diseases, including **hemolytic anemia**, liver **cirrhosis**, leukemia, malignant lymphoma and other infections and inflammatory diseases. Splenomegaly occurs in about 10% of **systemic lupus erythematosus** patients. Sometimes it is caused by recent viral infection, such as mononucleosis. An enlarged spleen may cause **pain** in the upper left side of the abdomen and a premature feeling of fullness at meals.

Diagnosis

Diagnosis of hypersplenism begins with review of symptoms and patient history and careful feeling (palpation) of the spleen. Sometimes, a physician can feel an enlarged spleen. X ray studies, such as **ultrasound** and computed tomography scan (CT scan), may help diagnose an enlarged spleen and possible underlying causes, such as tumors. Blood tests indicate decreases in white blood cells, red blood cells, or platelets. Another test measures red blood cells in the liver and spleen after injection of a radioactive substance and indicates areas where the spleen is holding on to large numbers of red cells or is destroying them.

Enlarged spleens are diagnosed using a combination of patient history; **physical examination**, including palpation of the spleen, if possible; and diagnostic tests. A history of fever and systemic symptoms may be present because of infection, malaria, or an inflammatory disorder. A **complete blood count** is taken to check counts of young red blood cells. **Liver function tests**, CT scans, and ultrasound exams can also help to detect an enlarged spleen.

Treatment

In secondary hypersplenism, the underlying disease must be treated to prevent further sequestration or destruction of blood cells, and possible spleen enlargement. Those therapies will be tried prior to removal of the spleen (**splenectomy**), which is avoided if possible. In severe cases, the spleen must be removed. Splenectomy will correct the effects of low blood cell concentrations in the blood.

Prognosis

Prognosis depends on the underlying cause and progression of the disease. Left untreated, spleen enlargement can lead to serious complications. Hypersplenism can also lead to complications due to decreased blood cell counts.

Prevention

Some of the underlying causes of hypersplenism or enlarged spleen can be prevented, such as certain forms of anemia and cirrhosis of the liver due to alcohol use. In other cases, the hypersplenism may not be preventable, as it is a complication to an underlying disorder.

Teresa Odle

Hypertension

Definition

Hypertension is high blood pressure. Blood pressure is the force of blood pushing against the walls of arteries as it flows through them. Arteries are the blood vessels that carry oxygenated blood from the heart to the body's tissues.

Demographics

Hypertension is a major health problem, especially because it has no symptoms. Many people have hypertension without knowing it. In the United States, about 67 million people age six and older have high blood

WWW.BOOKBAZ.IR

The effects of hypertension on the heart and kidney. Hypertension has caused renal atrophy and scarring, and left ventricular hypertrophy in the sectioned heart (at right). *(Dr. E. Walker/Photo Researchers, Inc.)*

pressure, which represents one in every three people. Hypertension is more common in men than women and in people over the age of 65 than in younger persons. More than half of all Americans over the age of 65 have hypertension. It also is more common in African Americans than in white Americans.

Description

As blood flows through arteries it pushes against the inside of the artery walls. The more pressure the blood exerts on the artery walls, the higher the blood pressure will be. The size of small arteries also affects the blood pressure. When the muscular walls of arteries are relaxed, or dilated, the pressure of the blood flowing through them is lower than when the artery walls narrow, or constrict.

Blood pressure is highest when the heart beats to push blood out into the arteries. When the heart relaxes to fill with blood again, the pressure is at its lowest point. Blood pressure when the heart beats is called systolic pressure. Blood pressure when the heart is at rest is called diastolic pressure. When blood pressure is measured, the systolic pressure is stated first and the diastolic pressure second. Blood pressure is measured in millimeters of mercury (mm Hg). For example, if a person's systolic pressure is 120 and diastolic pressure is 80, it is written as 120/80 mm Hg. The American Heart Association has long considered blood pressure less than 140 over 90 normal for adults. However, the National Heart, Lung, and Blood Institute in Bethesda, Maryland, released new clinical guidelines for blood pressure in 2003, lowering the standard normal readings. A normal reading was lowered to less than 120 over less than 80. This continues to be the guideline used to diagnosed the disorder.

Hypertension is serious because people with the condition have a higher risk for **heart disease** and other medical problems than people with normal blood pressure. Serious complications can be avoided by getting regular blood pressure checks and treating hypertension as soon as it is diagnosed.

If left untreated, hypertension can lead to the following medical conditions:

- arteriosclerosis, also called atherosclerosis
- heart damage or heart attack
- congestive heart failure
- stroke
- enlarged heart
- kidney damage
- vision problems
- memory problems
- chest pain (angina)
- problems getting and keeping a penile erection
- problems with arteries in the legs, leading to difficulty and pain while walking
- fluid in the lungs

Arteriosclerosis is hardening of the arteries. The walls of arteries have a layer of muscle and elastic tissue that makes them flexible and able to dilate and constrict as blood flows through them. High blood pressure can make the artery walls thicken and harden. When artery walls thicken, the inside of the blood vessel narrows. **Cholesterol** and fats are more likely to build up on the walls of damaged arteries, making them even narrower. **Blood clots** also can get trapped in narrowed arteries, blocking the flow of blood.

Arteries narrowed by arteriosclerosis may not deliver enough blood to organs and other tissues. Reduced or blocked blood flow to the heart can cause a **heart attack**. If an artery to the brain is blocked, a **stroke** can result.

Hypertension makes the heart work harder to pump blood through the body. The extra workload can make the heart muscle thicken and stretch. When the heart becomes too enlarged it cannot pump enough blood. If the hypertension is not treated, the heart may fail.

The kidneys remove the body's wastes from the blood. If hypertension thickens the arteries to the kidneys, less waste can be filtered from the blood. As the condition worsens, the kidneys fail and wastes build up in the blood. Dialysis or a kidney transplant are needed when the kidneys fail. About 25% of people who receive **kidney dialysis** have kidney failure caused by hypertension.

Risk factors

Even though the cause of most hypertension is not known, some people have risk factors that increase their chance of developing hypertension. Many of these risk factors can be avoided to lower the chance of developing hypertension or as part of a treatment program to lower blood pressure.

Risk factors for hypertension include:

- age over 60
- male sex
- race
- heredity
- salt sensitivity
- obesity
- diabetes
- inactive lifestyle
- heavy alcohol consumption
- use of oral contraceptives

Some people inherit a tendency for hypertension. People with family members who have hypertension are more likely to develop it than those whose relatives are not hypertensive. People with these risk factors can avoid or eliminate other risk factors to lower their chance of developing hypertension. A 2003 report found that the rise in incidence of high blood pressure among children is most likely due to an increase in the number of overweight and obese children and adolescents. Diet and sedentariness seem to be significantly associated with this increase.

Causes and symptoms

Many different actions or situations can normally raise blood pressure. Physical activity can temporarily raise blood pressure. Stressful situations can make blood pressure go up; when the **stress** goes away, blood pressure usually returns to normal. These temporary increases in blood pressure are not considered hypertension. A diagnosis of hypertension is made only when a person has multiple high blood pressure readings over a period of time.

The cause of hypertension is not known in 90–95% of the people who have it. Hypertension without a known cause is called primary or essential hypertension.

When a person has hypertension caused by another medical condition, it is called secondary hypertension. Secondary hypertension can be caused by a number of different illnesses. Many people with kidney disorders have secondary hypertension. The kidneys regulate the balance of salt and water in the body. If the kidneys cannot rid the body of excess salt and water, blood pressure goes up. Kidney infections, a narrowing of the arteries that carry blood to the kidneys, called **renal artery stenosis**, and other kidney disorders can disturb the salt and water balance.

Cushing's syndrome and tumors of the pituitary and adrenal glands often increase levels of the adrenal gland hormones cortisol, adrenalin, and aldosterone, which can cause hypertension. Other conditions that can cause hypertension are blood vessel diseases, thyroid gland disorders, some prescribed drugs, **alcoholism**, and **pregnancy**.

One of the most dangerous features of hypertension is the fact that it does not usually cause any symptoms. Individuals may not be aware that they have the condition, or they may mistakenly downplay its importance, simply because it is not causing any discernible problems. Without treatment, the deleterious effects of hypertension progress unchecked.

When blood pressure becomes extremely high, for example over 180/110 mmHg (termed malignant hypertension), symptoms such as **headache**, visual disturbances, **anxiety**, and **shortness of breath** may occur. If left untreated, stroke may supervene, or a hypertensive crisis, in which organs cannot receive an adequate blood supply and begin to fail, may occur.

Diagnosis

Examination

Because hypertension does not cause symptoms, it is important to have blood pressure checked regularly. Blood pressure is measured with an instrument called a sphygmomanometer. A cloth-covered rubber cuff is wrapped around the upper arm and inflated. When the cuff is inflated, an artery in the arm is squeezed to momentarily stop the flow of blood. Then, the air is let out of the cuff while a stethoscope placed over the artery is used to detect the sound of the blood spurting back through the artery. This first sound is the systolic pressure, the pressure when the heart beats. The last sound heard as the rest of the air is released is the diastolic pressure, the pressure between heart beats. Both sounds are recorded on the mercury gauge on the sphygmomanometer.

Normal blood pressure is defined by a range of values. Blood pressure lower than 120/80 mm Hg is considered normal. A number of factors such as **pain**, stress, or anxiety can cause a temporary increase in blood pressure. For this reason, hypertension is not diagnosed on one high blood pressure reading. If a blood pressure reading is 120/80 or higher for the first time, the physician will have the person return for

WWW.BOOKBAZ.IR

another blood pressure check. Diagnosis of hypertension usually is made based on two or more readings after the first visit.

Systolic hypertension of the elderly is common and is diagnosed when the diastolic pressure is normal or low, but the systolic is elevated, e.g., 170/70 mm Hg. This condition usually co-exists with hardening of the arteries (atherosclerosis).

Blood pressure measurements are classified in stages, according to severity:

- normal blood pressure: less than 120/80 mm Hg
- pre-hypertension: 120–129/80–89 mm Hg
- Stage 1 hypertension: 140–159/90–99 mm Hg
- Stage 2 hypertension: at or greater than 160–179/100–109 mm Hg

A typical **physical examination** to evaluate hypertension includes:

- medical and family history
- physical examination
- ophthalmoscopy: Examination of the blood vessels in the eye
- chest x ray
- electrocardiograph (ECG)
- blood and urine tests

The medical and family history help the physician determine if the patient has any conditions or disorders that might contribute to or cause the hypertension. A family history of hypertension might suggest a genetic predisposition for hypertension.

The physical exam may include several blood pressure readings at different times and in different positions. The physician uses a stethoscope to listen to sounds made by the heart and blood flowing through the arteries. The pulse, reflexes, and height and weight are checked and recorded. Internal organs are palpated, or felt, to determine if they are enlarged.

Because hypertension can cause damage to the blood vessels in the eyes, the eyes may be checked with a instrument called an ophthalmoscope. The physician will look for thickening, narrowing, or hemorrhages in the blood vessels.

Tests

A chest x ray can detect an enlarged heart, other vascular (heart) abnormalities, or lung disease.

An electrocardiogram (ECG) measures the electrical activity of the heart. It can detect if the heart muscle is enlarged and if there is damage to the heart muscle from blocked arteries.

Urine and blood tests may be done to evaluate health and to detect the presence of disorders that might cause hypertension.

Treatment

Traditional

There is no cure for primary hypertension, but blood pressure can almost always be lowered with the correct treatment. The goal of treatment is to lower blood pressure to levels that will prevent heart disease and other complications of hypertension. In secondary hypertension, the disease that is responsible for the hypertension is treated in addition to the hypertension itself. Successful treatment of the underlying disorder may cure the secondary hypertension.

Guidelines advise that clinicians work with patients to agree on blood pressure goals and develop a treatment plan for the individual patient. Actual combinations of medications and lifestyle changes will vary from one person to the next. Treatment to lower blood pressure may include changes in diet, getting regular **exercise**, and taking antihypertensive medications. Patients falling into the pre-hypertension range who do not have damage to the heart or kidneys often are advised to make lifestyle changes only. A 2003 report of a clinical trial showed that adults with elevated blood pressures lowered them as much as 38% by making lifestyle changes and participating in the **DASH diet**, which encourages eating more fruit and vegetables.

Drugs

Patients with stage 1 hypertension may be advised to take antihypertensive medication. Numerous drugs have been developed to treat hypertension. The choice of medication depends on the stage of hypertension, side effects, other medical conditions the patient may have, and other medicines the patient is taking.

If treatment with a single medicine fails to lower blood pressure enough, a different medicine may be tried or another medicine may be added to the first. Patients with more severe hypertension may initially be given a combination of medicines to control their hypertension. Combining antihypertensive medicines with different types of action often controls blood pressure with smaller doses of each drug than would be needed for just one.

Antihypertensive medicines fall into several classes of drugs:

- diuretics
- beta-blockers

- calcium channel blockers
- angiotensin converting enzyme inhibitors (ACE inhibitors)
- alpha-blockers
- alpha-beta blockers
- vasodilators
- peripheral acting adrenergic antagonists
- centrally acting agonists

Diuretics help the kidneys eliminate excess salt and water from the body's tissues and the blood. This reduces the swelling caused by fluid buildup in the tissues. The reduction of fluid dilates the walls of arteries and lowers blood pressure. Diuretics are recommended as the first drug of choice for most patients with high blood pressure and as part of any multi-drug combination.

Beta-blockers lower blood pressure by acting on the nervous system to slow the heart rate and reduce the force of the heart's contraction. They are used with caution in patients with **heart failure**, **asthma**, diabetes, or circulation problems in the hands and feet.

Calcium channel blockers block the entry of **calcium** into muscle cells in artery walls. Muscle cells need calcium to constrict, so reducing their calcium keeps them more relaxed and lowers blood pressure.

ACE inhibitors block the production of substances that constrict blood vessels. They also help reduce the build-up of water and salt in the tissues. They often are given to patients with heart failure, **kidney disease**, or diabetes. ACE inhibitors may be used together with diuretics.

Alpha-blockers act on the nervous system to dilate arteries and reduce the force of the heart's contractions.

Alpha-beta blockers combine the actions of alpha and **beta blockers**.

Vasodilators act directly on arteries to relax their walls so blood can move more easily through them. They lower blood pressure rapidly and are injected in hypertensive emergencies when patients have dangerously high blood pressure.

Peripheral acting adrenergic antagonists act on the nervous system to relax arteries and reduce the force of the heart's contractions. They usually are prescribed together with a diuretic. Peripheral acting adrenergic antagonists can cause slowed mental function and lethargy.

Centrally acting agonists also act on the nervous system to relax arteries and slow the heart rate. They are usually used with other antihypertensive medicines.

Home remedies

Lifestyle changes that may reduce blood pressure by 5 to 10 mm Hg include:

- reducing salt intake
- reducing fat intake
- losing weight
- getting regular exercise
- quitting smoking
- reducing alcohol consumption
- managing stress

Prognosis

There is no cure for hypertension. However, it can be well controlled with proper treatment. Therapy with a combination of lifestyle changes and antihypertensive medicines can keep blood pressure at levels that will not cause damage to the heart or other organs. The key to avoiding serious complications of hypertension is to detect and treat it before damage occurs. Because antihypertensive medicines control blood pressure, but do not cure it, patients must continue taking the medications to maintain reduced blood pressure levels and avoid complications.

Prevention

The risk of developing hypertension can be reduced by:

- reducing salt intake
- reducing fat intake
- losing weight
- getting regular exercise
- quitting smoking
- reducing alcohol consumption
- managing stress

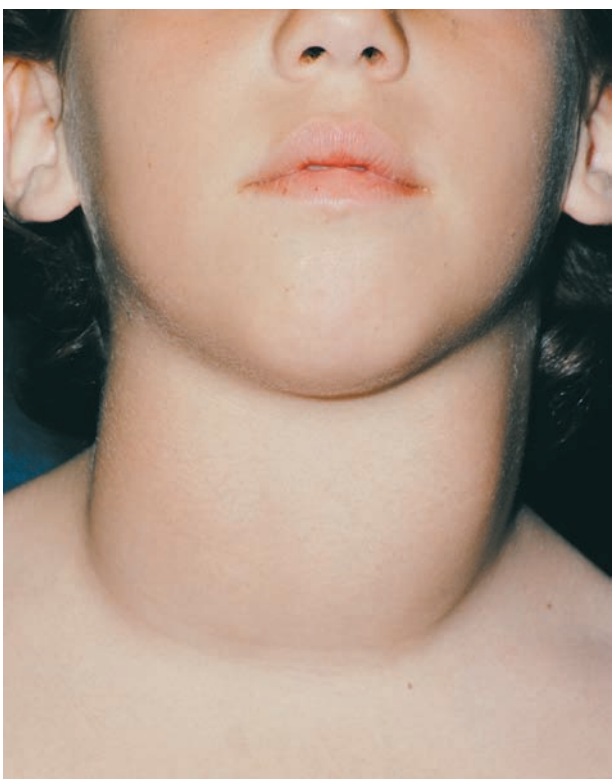
Hyperthermia *see* **Fever**

Hyperthyroidism

Definition

Hyperthyroidism is the overproduction of **thyroid hormones** by an overactive thyroid gland. More specifically, the thyroid gland produces too much of a hormone called thyroxine.



A symptom of hyperthyroidism is the enlargement of the thyroid gland. *(© Lester V. Bergman/Corbis.)*

The term hyperthyroidism covers any disease that results in overabundance of thyroid hormone. Other names for hyperthyroidism, or specific diseases within the category, include Graves' disease, diffuse toxic **goiter**, Basedow's disease, Parry's disease, and thyrotoxicosis.

Demographics

Hyperthyroidism is a fairly common disorder; the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) estimates that about 1% of the population of the United States and Canada has some form of hyperthyroidism. It is primarily a disease of adults; most patients are 35 or older at the time of diagnosis. Only about 5% of patients are younger than 15 years of age. The peak age for hyperthyroidism caused by Graves' disease is 35–40 years; hyperthyroidism caused by multinodular goiter is more common in adults over 50 than in younger adults.

The disease is 10 times more common in women than in men, and the annual incidence of hyperthyroidism in the United States is about 1 per 1,000 women. About 7% of women of childbearing age develop postpartum **thyroiditis** in the year after they give birth. Between 3% and 7% of adults in the United States develop thyroid nodules. Occult hyperthyroidism may occur in patients over 65 and is characterized by a distinct lack of typical symptoms. Diffuse toxic goiter occurs in as many as 80% of patients with hyperthyroidism.

Among children, about five times as many girls as boys develop hyperthyroidism. Almost all cases of pediatric hyperthyroidism are the form called Graves' disease. There is a form of hyperthyroidism called neonatal Graves' disease, which occurs in infants born of mothers with Graves' disease. Children with such other conditions as trisomy 21 (**Down syndrome**), Addison's disease, diabetes, **systemic lupus erythematosus**, **rheumatoid arthritis**, **myasthenia gravis**, **vitiligo**, **pernicious anemia**, and immune thrombocytopenic purpura are more likely to develop Graves' disease.

Hyperthyroidism is equally common among Caucasians, Asians, and Hispanics in the United States but is less common among African Americans.

Description

Located in the front of the neck, the thyroid gland is a butterfly-shaped structure lying between the Adam's apple and the collarbone. It takes its name

from a Greek word meaning "shield." It consists of two lobes about 2 in. (5 cm) in length (in adults) connected by a thin strip of tissue called the isthmus. The thyroid gland weighs about 0.1 oz. (3 g) in newborns and 0.6–1.5 oz. (17–43 g) in adults. One of the largest endocrine glands in the body, the thyroid controls the rate at which the body **burns** energy, its sensitivity to other hormones, and its manufacture of proteins.

The thyroid gland produces two hormones: thyroxine (T_4) and triiodothyronine (T_3), which regulate the body's metabolic rate by helping to form protein ribonucleic acid (RNA) and increasing oxygen absorption in every cell. In turn, the production of these hormones is controlled by thyroid-stimulating hormone (TSH), which is produced by the pituitary gland. Hyperthyroidism occurs when production of the thyroid hormones increases despite the level of TSH being produced. The excessive amount of thyroid hormones in the blood increases the body's metabolism, producing both mental and physical symptoms.

Risk factors

Risk factors for hyperthyroidism include:

- Female sex
- Age over 60
- Family history of thyroid disorders. Some genes have been identified that increase a person's susceptibility to autoimmune thyroid disease.
- Personal history of thyroid surgery or goiter
- Having type 1 diabetes, pernicious anemia, or primary adrenal insufficiency
- Pregnancy
- Giving birth within the past 6 months
- Eating large amounts of iodine-containing foods
- Use of medications containing iodine, particularly amiodarone (Cordarone), a drug given to treat irregular heart rhythms

Causes and symptoms

Causes

Hyperthyroidism is often associated with the body's production of autoantibodies in the blood that cause the thyroid to grow and secrete excess thyroid hormone. This condition, as well as other forms of hyperthyroidism, may be inherited. It accounts for 70–75% of cases of hyperthyroidism.

Other causes of hyperthyroidism include multinodular goiter or Plummer's disease (about 15–20% of cases of hyperthyroidism), a condition in which adenomas (nodules or lumps) form within the thyroid gland and cause it to secrete a larger than normal amount of thyroid hormone, and thyroiditis, a condition in which a malfunction of the immune system or a viral infection causes the thyroid gland to leak thyroid hormone. Last, hyperthyroidism can be caused by taking too much thyroid hormone in tablet form. In a few very rare cases, hyperthyroidism can be caused by a malignant (cancerous) tumor in the thyroid gland.

Symptoms

Regardless of the cause or age of the patient, hyperthyroidism produces the same symptoms, including sudden weight loss with increased appetite, **shortness of breath** and **fatigue**, intolerance of heat, heart **palpitations**, increased frequency of bowel movements, warm and smooth skin, weak muscles, **tremors**, **anxiety**, and difficulty sleeping. Women of childbearing age may also notice decreased menstrual flow and irregular menstrual cycles.

The symptoms of hyperthyroidism are often less noticeable in older adults, and may consist mainly of an increased heart rate, heat intolerance, and a tendency to become tired during ordinary activities. In addition, **beta blockers** (a type of heart medication) can mask the symptoms of hyperthyroidism in seniors.

Patients with Graves' disease often have a goiter (visible enlargement of the thyroid gland), although as many as 10% do not. These patients may also have bulging eyes. Thyroid storm, a serious form of hyperthyroidism, may show up as sudden and acute symptoms, some of which mimic typical hyperthyroidism, as well as the addition of **fever** (104°F [40°C] or higher), substantial weakness, extreme restlessness, confusion, emotional swings or **psychosis**, or **coma**. Fortunately, such a fulminant course of Graves' disease is rare in children and adolescents.

Babies with neonatal Graves' disease may have **prematurity**, airway obstruction, and **heart failure**. Death occurs in as many as 16% of these babies, and other complications from which survivors may suffer include craniosynostosis (early closure of the sutures of the skull, which can result in compression of the growing brain), and developmental delay.

Diagnosis

The diagnosis of hyperthyroidism is based on a combination of patient history, a **physical examination**, and the results of laboratory and imaging tests. In most cases, patients are evaluated and treated by an endocrinologist rather than a family doctor.

WWW.BOOKBAZ.IR

KEY TERMS

Adenoma—The medical term for a benign (noncancerous) tumor that originates in a gland. Thyroid nodules are one type of adenoma.

Endocrine gland—Any gland that makes hormones and secretes them directly into the bloodstream.

Endocrinologist—A doctor who specializes in diagnosing and treating disorders of the endocrine glands and the hormones they secrete.

Fulminant—Referring to a disease process that is explosive in onset, severe, and potentially deadly.

Goiter—Chronic enlargement of the thyroid gland.

Gonads—Organs that produce gametes (eggs or sperm), such as the ovaries and testes.

Graves' disease—An autoimmune disorder of the thyroid gland, in which the gland swells to twice its normal size and secretes too much thyroid hormone. Graves' disease accounts for 70–75% of cases of hyperthyroidism. It is named for an Irish doctor named Robert James Graves, who described a case of the disorder in 1835.

Hormone—A chemical released by specialized cells that affects cells in other parts of the body. Hormones regulate such body processes as growth, metabolism, the immune system, reproduction, hunger, and mood.

Multinodular goiter—A condition in which benign lumps of tissue (nodules) form within the thyroid gland and cause it to secrete too much thyroid hormone. It is also called Plummer's disease.

Palpitations—Rapid and forceful heartbeat.

Postpartum—After childbirth.

Radioisotope—One of two or more atoms with the same number of protons but a different number of neutrons with a nuclear composition. In nuclear scanning, radioactive isotopes are used as a diagnostic agent.

Thyroid storm—A rare but potentially life-threatening complication of hyperthyroidism, characterized by fever over 104°F (40°C), irregular heart rhythm, vomiting, diarrhea, dehydration, coma, and death.

Thyroidectomy—Surgical removal of the thyroid gland.

Thyroiditis—Inflammation of the thyroid gland. It can be caused by a viral infection, a malfunction of the immune system, or certain medications.

Thyrotoxicosis—Another term for hyperthyroidism.

Vitiligo—A chronic skin disorder that causes loss of pigmentation (color) from patches of skin, most often on the face, hands, and wrists.

Examination

Patients concerned that they may have nodules in their thyroid or an enlarged thyroid can conduct a neck check at home by examining their neck below the Adam's apple and above the collarbone while swallowing water and looking in a handheld mirror.

An endocrinologist will look for physical signs and symptoms indicated by the patient's history during an office examination. The patient will typically be asked to lift the head and swallow several times while the doctor feels the part of the neck containing the thyroid gland. On inspection, the physician may note such symptoms as a goiter, warm, smooth, and moist skin, eye bulging or a staring gaze, high blood pressure, irregular heart rhythm, hyperactivity, overactive reflexes, tremor, and muscle weakness. **Pregnancy** or recent **childbirth** or a family history of thyroid disorders may also be clues to a diagnosis of hyperthyroidism.

Tests

A simple blood test can be performed to determine the amount of thyroid hormone in the patient's blood. The American Thyroid Association recommends that adults, particularly women, have this blood test to detect thyroid problems every five years starting at age 35. The diagnosis is usually straightforward with this combination of clinical history, physical examination, and routine blood hormone tests. Radioimmunoassay, a test to show concentrations of thyroid hormones with the use of a radioisotope mixed with fluid samples, helps confirm the diagnosis.

A thyroid scan is a nuclear medicine procedure involving injection of a radioisotope dye that will tag the thyroid and help produce a clear image of inflammation or involvement of the entire thyroid. Other tests can determine thyroid function and thyroid-stimulating hormone levels. Ultrasonography, **computed tomography scans** (CT scan), and **magnetic resonance imaging** (MRI) may provide visual confirmation of a diagnosis or help to determine the extent of involvement.

Procedures

The doctor may also order a fine needle aspiration biopsy (FNAB), a procedure in which the doctor inserts a thin needle into a suspected thyroid nodule to extract a sample of cells for examination under a microscope. The doctor usually uses an **ultrasound** monitor to guide the needle. A FNAB can be performed in an outpatient clinic or a doctor's office; it is safer and less invasive than an open surgical biopsy.

Treatment

Traditional

Treatment of hyperthyroidism will depend on the specific disease and individual circumstances such as age, severity of disease, and other conditions affecting a patient's health. No single approach to treatment works for all patients.

Drugs

Hyperthyroidism is usually treated with medications whenever possible. The two types of drugs most often prescribed are antithyroid drugs and radioactive iodine.

ANTITHYROID DRUGS. Antithyroid drugs are often administered to help the patient's body cease overproduction of thyroid hormones. The antithyroid drugs most commonly prescribed are methimazole (Tapazole) and propylthiouracil (PTU). About 20–30% of patients with Graves' disease will have long-term remission of hyperthyroidism after treatment with antithyroid drugs for a period of 12–18 months. It takes several weeks or months for antithyroid drugs to bring the patient's level of thyroid hormone into the normal range. Patients may be given beta blockers for symptom relief during this period.

Antithyroid drugs are also used in preparation for either radioiodine treatment or surgery in patients diagnosed with multinodular goiter. These medications may work for young adults, pregnant women, and others. Women who are pregnant should be treated with the lowest dose required to maintain thyroid function in order to minimize the risk of **hypothyroidism** in the infant.

Antithyroid drugs can have unpleasant side effects, such as **rashes**, **itching**, or increased susceptibility to infection due to a decreased level of white blood cells. In rare cases these medications can lead to liver failure.

RADIOACTIVE IODINE. Radioactive iodine (iodine-131) is often prescribed to damage cells that make thyroid hormone. The cells need iodine to make the hormone, so they will absorb any iodine found in the body. The patient may take an iodine capsule daily for several weeks, resulting in the eventual shrinkage of the thyroid in size, reduced hormone production and a return to normal blood levels. Some patients may receive a single larger oral dose of radioactive iodine to treat the disease more quickly. This should only be done for patients who are not of reproductive age or are not planning to have children, since a large amount can concentrate in the reproductive organs (gonads). The risk of long-term side effects is low. Radioactive iodine has been used for over 60 years to treat patients with hyperthyroidism and doctors have followed these patients carefully.

Most patients who are given iodone-131 eventually develop hypothyroidism, which is an abnormally low level of thyroid hormone. Most endocrinologists do not consider this side effect of iodine-131 to be a major problem because hypothyroidism is easier to treat and has fewer long-term complications than hyperthyroidism.

BETA BLOCKERS. Beta blockers may be used in the treatment of patients with hyperthyroidism even though they do not suppress the activity of the thyroid gland. They are useful in regulating the patient's heart rhythm and reducing such symptoms as palpitations, tremor, and nervousness until antithyroid medications can begin to take effect. The beta blockers most often prescribed for hyperthyroidism are the longer-acting drugs like atenolol (Tenormin), metoprolol (Lopressor), and nadolol (Corgard).

Surgery

Some patients may undergo surgery to treat hyperthyroidism. Surgery is usually recommended when the results of a FNAB indicate that the patient has a malignancy in the thyroid, or when the thyroid gland is so enlarged that it is putting pressure on the patient's windpipe or esophagus.

Most commonly, patients treated with **thyroidectomy** in the form of partial or total removal of the thyroid have large goiter and have relapses, even after repeated attempts to address the disease through drug therapy. Some patients may be candidates for surgery because they were not good candidates for iodine therapy, or refused iodine administration. Patients receiving thyroidectomy or iodine therapy must be carefully monitored for years to watch for signs of hypothyroidism, or insufficient production of thyroid hormones, which can occur as a complication of thyroid production suppression.

WWW.BOOKBAZ.IR

Alternatives

Consumption of such foods as broccoli, Brussels sprouts, cabbage, cauliflower, kale, rutabagas, spinach, turnips, peaches, and pears can help naturally suppress thyroid hormone production. Caffeinated drinks and dairy products should be avoided. Under the supervision of a trained physician, high dosages of certain vitamin/mineral combinations can help to alleviate hyperthyroidism.

Prognosis

Hyperthyroidism is generally treatable and carries a good prognosis. Most patients lead normal lives with proper treatment. Thyroid storm, however, can be life-threatening and can lead to heart, liver, or kidney failure. This form of fulminant hyperthyroidism is rare in children and adolescents.

Hyperthyroidism is associated with an increased risk of Alzheimer's disease in later life even when the thyroid dysfunction has been successfully treated. The reason for this association is not fully understood as of 2015.

Prevention

Although a periodic neck check at home cannot prevent hyperthyroidism in the strict sense of prevention, it can help in detecting the condition earlier rather than later.

There are no known prevention methods for hyperthyroidism, since its causes were either inherited or not completely understood as of 2015. The best prevention tactic is knowledge of family history and close attention to symptoms and signs of the disease. Careful attention to prescribed therapy can prevent complications of the disease.

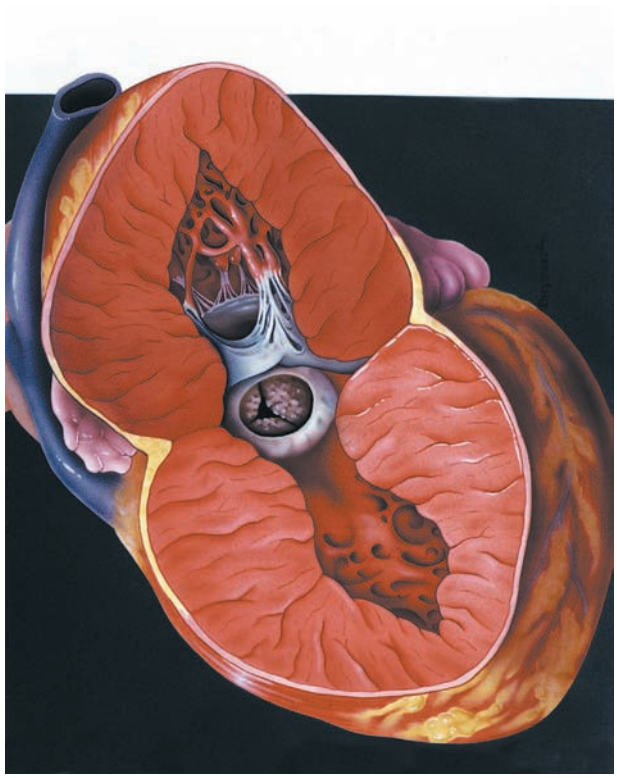
Hypertrophic cardiomyopathy

Definition

Cardiomyopathy is an ongoing disease process that damages the muscle wall of the lower chambers of the heart. Hypertrophic cardiomyopathy is a form of cardiomyopathy in which the walls of the heart's chambers thicken abnormally. Other names for hypertrophic cardiomyopathy are idiopathic hypertrophic subaortic stenosis and asymmetrical septal hypertrophy.



This illustration shows hypertrophic muscle in the heart. The abnormally thick wall of muscle prevents the chambers from stretching to fill up with blood, making the heart less efficient. *(Custom Medical Stock Photo, Inc.)*

Description

Hypertrophic cardiomyopathy usually appears in young people, often in athletes. For this reason it is sometimes called athletic heart muscle disease. However, people of any age can develop hypertrophic cardiomyopathy. Often there are no symptoms of hypertrophic cardiomyopathy. Sudden death can occur, caused by a heart arrhythmia. The American Heart Association reports that 36% of young athletes who die suddenly have probable or definite hypertrophic cardiomyopathy.

Hypertrophic cardiomyopathy is the result of abnormal growth of the heart muscle cells. The wall between the heart's chambers (the septum) may become so thickened that it blocks the flow of blood through the lower left chamber (left ventricle). The thickened wall may push on the heart valve between the two left heart chambers (mitral valve), making it leaky. The thickened muscle walls also prevent the heart from stretching as much as it should to fill with blood.

Causes and symptoms

The cause of hypertrophic cardiomyopathy is not known. In about one-half of cases, the disease is inherited. An abnormal gene has been identified in these patients. In cases that are not hereditary, a gene that was normal at birth may later become abnormal.

Often people with hypertrophic cardiomyopathy have no symptoms. Unfortunately, the first sign of the condition may be sudden death caused by an abnormal heart rhythm. When symptoms do appear, they include **shortness of breath** on exertion, **dizziness**, **fainting**, **fatigue**, and chest **pain**.

Diagnosis

The diagnosis is based on the patient's symptoms (if any), a complete **physical examination**, and tests that detect abnormalities of the heart chambers. Usually, there is an abnormal heart murmur that worsens with the **Valsalva maneuver**. The electrocardiogram (ECG), which provides a record of electrical changes in the heart muscle during the heartbeat, also is typically abnormal.

Sometimes, a routine chest x ray may show that the heart is enlarged. **Echocardiography**, a procedure that produces images of the heart's structure, is

WWW.BOOKBAZ.IR

usually done. These images can show if the heart wall is thickened and if there are any abnormalities of the heart valves.

Treatment

Treatment of hypertrophic cardiomyopathy usually consists of taking medicines and restricting strenuous **exercise**. Drugs called **beta blockers** and **calcium channel blockers** are usually prescribed. Beta blockers reduce the force of the heart's contractions. **Calcium** channel blockers can help improve the flexibility of the heart muscle walls, allowing them to stretch more. **Antiarrhythmic drugs** may also be given to prevent abnormal heart rhythms.

Patients with hypertrophic cardiomyopathy are also told to avoid strenuous exercise to reduce the risk of passing out or sudden death.

In some cases, if the medications do not help relieve symptoms, surgery may help. In an operation called myotomy-myectomy a piece of the septum is removed to improve blood flow through the heart chamber.

Some patients have **pacemakers** and/or defibrillators implanted to help control the heart rate and rhythm. Pacemakers and defibrillators provide electrical impulses to the heart, which can return the heart beat to a normal rhythm.

If these treatment methods fail and a patient develops **heart failure**, a heart transplant may be necessary.

Prognosis

Some people with hypertrophic cardiomyopathy may not have obstructed blood flow and may never experience symptoms. Others may only experience mild symptoms. With treatment, symptoms may improve. In some patients, the disease may progress to heart failure.

Prevention

While hypertrophic cardiomyopathy cannot be prevented, precautionary measures may prevent sudden deaths. Anyone planning to take part in a program of strenuous competitive exercise should have a checkup by a physician first. A physical examination before athletic participation can usually, but not always, detect conditions like hypertrophic cardiomyopathy. Anyone who experiences symptoms of shortness of breath, tiredness, or fainting with exercise should see a physician.

Hypervitaminosis *see* **Vitamin toxicity**

Hyphema

Definition

A hyphema is an accumulation of blood in the front (anterior) chamber of the eye. It is usually caused by blunt eye **trauma**.

Description

The anterior chamber (AC) is located behind the front of the eye. The AC is filled with a fluid called aqueous humor. This fluid helps form a cushion for the eye and provides an important route for nutrient and waste transport. Contusive forces from high velocity projectiles (approximately 34% of emergency room cases) such as a rock, crab apples, ice balls, badminton birds, and bungee cords can tear local blood vessels in the eye. Blunt impact from a basketball or racketball accounts for about 62% of cases. Tearing a small blood vessel can cause seepage of blood into a visible layer portion of the AC, causing the affected person to have a red eye.

Causes and symptoms

Hyphema is caused by blunt, projectile, or explosion (about 4% of cases) injuries. These injuries cause a local blood vessel in the eye to tear, filling the front portion of the AC with blood. The initial complaint is a dramatic decrease in vision that eventually gets better as blood seeps towards the back of the eye. Patients will have extreme **pain**, an increase in intraocular pressure (the pressure inside the eye), and nausea. Patients usually will show a red eye and a recent history of trauma. Patients are vulnerable to more bleeding three to five days post injury.

Diagnosis

All persons with hyphema must be examined by an ophthalmologist (a physician who specializes in the medical and surgical care of the eye). Usually, the clinician will use an ophthalmoscope to visualize the internal structures and damage. In some cases there may be small microscopic bleeds that may form clots (microhyphema) and require specialized instrumentation (a slit lamp) for visualization.

Treatment

Bloodthinners, such as **aspirin** and **nonsteroidal anti-inflammatory drugs**, should be avoided. In most cases the affected person can be medically managed on an outpatient basis. The eye should be shielded, but not patched. The patient should be placed on bed rest with the head elevated 45°. This position allows blood to leave the AC allowing for better vision. Several studies suggest administering medications (aminocaproic acid) that stabilize clot formation, reducing the possibility of increased bleeding.

Prognosis

The outcome depends on the severity of the trauma. Most cases progress well with conservative treatment. Some cases may develop an increase in the pressure within the eye (**glaucoma**). If this develops the hyphema must be surgically removed by an ophthalmologist. In patients who have a preexisting blood disorder, surgical evacuation should be considered to prevent damage to the optic nerve (the nerve that transmits impulses for processing in the brain).

Prevention

The American Academy of Ophthalmology recommends special eyewear made of polycarbonate lenses when at risk of eye injury. This type of lens has sufficient impact resistance.

Hypnosis *see* **Hypnotherapy**

Hypnotherapy

Definition

Hypnotherapy is the treatment of a variety of health conditions by hypnotism or by inducing prolonged sleep.

Pioneers in this field, such as James Braid and James Esdaile, discovered that hypnosis could be used to successfully anesthetize patients for surgeries. James Braid accidentally discovered that one of his patients began to enter a hypnotic state while staring at a fixed light as he waited for his **eye examination** to begin. Since mesmerism had fallen out of favor, Braid coined the term hypnotism, which is derived from the Greek word for sleep. Braid also used the techniques of monotony, rhythm, and imitation to assist in inducing a hypnotic state. These techniques are still in use.

Around 1900, there were very few preoperative anesthetic drugs available. Patients were naturally apprehensive when facing surgery. One out of 400 patients would die, not from the surgical procedure, but from the **anesthesia**. Dr. Henry Munro was one of the first physicians to use hypnotherapy to alleviate patient fears about having surgery. He would get his patients into a hypnotic state and discuss their fears with them, telling them they would feel a lot better following surgery. Ether was the most common anesthetic at that time, and Dr. Munro found that he was able to perform surgery using only about 10% of the usual amount of ether.

Purpose

Hypnotherapy is used in a number of fields including **psychotherapy**, surgery, dentistry, research, and medicine. Hypnotherapy is commonly used as an alternative treatment for a wide range of health conditions, including weight control, **pain management**, and **smoking** cessation. It is also used to control **pain** in a variety of conditions such as **headache**, facial **neuralgia**, arthritis, **burns**, musculoskeletal disorders, **childbirth**, and many more. Hypnotherapy is being used in place of anesthesia, particularly in patients who prove to be allergic to anesthetic drugs, for surgeries such as hysterectomies, cesarean sections, certain cardiovascular procedures, **thyroidectomy**, and others. Dentistry is using hypnotherapy with success on patients who are allergic to all types of novocaine drugs. Hypnotherapy is also useful in helping patients overcome **phobias**.

Hypnotherapy is used for nonmedical patients as well as those who wish to overcome bad habits. Hypnotherapy has been shown to help those who have

WWW.BOOKBAZ.IR

performance **anxiety**, such as in sports, and speaking in public. In academic applications, it has also been shown to help with learning, participating in the classroom, concentrating, studying, focusing attention span, improving memory, and helping remove mental blocks about particular subjects.

In more general areas, hypnotherapy has been found to be beneficial for problems such as motivation, procrastination, decision making, personal achievement and development, job performance, buried or repressed memories, relaxation, and **stress** management.

Description

Origins

Hypnotherapy is thought to date back to the healing practices of ancient Greece and Egypt. Many religions such as Judaism, Christianity, Islam, and others have attributed trance-like behavior to spiritual or divine possession.

Austrian physician, Franz Mesmer (1734–1815), is credited with being the first person to scientifically investigate the idea of hypnotherapy, in 1779, to treat a variety of health conditions. Mesmer studied medicine at the University of Vienna and received his medical degree in 1766. Mesmer is believed to have been the first doctor to understand the relationship of psychological **trauma** to illness. He induced a trance-like state, which became known as mesmerism, in his patients to successfully treat nervous disorders. These techniques became the foundation for modern-day hypnotherapy.

Mesmer's original interest was in the effect of celestial bodies on human lives. He later became interested in the effects of magnetism, and found that magnets could have tremendous healing effects on the human body. Mesmer believed that the human body contained a magnetic fluid that promoted health and well being. It was thought that any blockage to the normal flow of this magnetic fluid would result in illness, and that the use of the mesmerism technique could restore the normal flow.

Mesmer performed his technique by passing his hands up and down the patient's body. The technique was supposed to transmit magnetic fluid from his hands to the bodies of his patients. During this time, there was no clear delineation between health conditions that were physical or psychological in nature. Although Mesmer did not realize it at that time, his treatments were most effective for those conditions that were primarily psychosomatic.

Mesmer's technique appeared to be quite successful in the treatment of his patients, but he was the subject of scorn and ridicule from the medical profession. Because of all the controversy surrounding mesmerism, and because Mesmer's personality was quite eccentric, a commission was convened to investigate his techniques and procedures. A very distinguished panel of investigators included Benjamin Franklin, the French chemist Antoine-Laurent Lavoisier, and physician Jacques Guillotin. The commission acknowledged that patients did seem to obtain noticeable relief from their conditions, but the whole idea was dismissed as being medical quackery.

It took more than 200 years for hypnotherapy to be incorporated into medical treatment. In 1955, the British Medical Association approved the use of hypnotherapy as a valid medical treatment, with the American Medical Association (AMA) giving its approval in 1958.

Hypnotherapy involves achieving a psychological state of awareness that is different from the ordinary state of consciousness. While in a hypnotic state, a variety of phenomena can occur. These phenomena include alterations in memory, heightened susceptibility to suggestion, **paralysis**, sweating, and blushing. All of these changes can be produced or removed in the hypnotic state. Many studies have shown that roughly 90% of the population is capable of being hypnotized.

This state of awareness can be achieved by relaxing the body, focusing on breathing, and shifting attention away from the external environment. In this state, the patient has a heightened receptivity to suggestion. The usual procedure for inducing a hypnotic trance in another person is by direct command repeated in a soothing, monotonous tone of voice.

Preparations

Ideally, the following conditions should be present to successfully achieve a state of hypnosis:

- willingness to be hypnotized
- rapport between the patient or client and the hypnotherapist
- a comfortable environment that is conducive to relaxation

Precautions

Hypnotherapy can have negative outcomes. When used as entertainment, people have been hypnotized to say or do things that would normally embarrass them. There have been instances where people already dangerously close to psychological breakdown have been pushed into an emotional crisis during what was supposed to be a harmless demonstration of hypnosis.

A statement from the World Hypnosis Organization (WHO) warns against performing hypnosis on patients with **psychosis**, organic psychiatric conditions, or antisocial **personality disorders**. Because there are no standard licensing requirements, in the wrong hands, there is a risk that the hypnotist will have difficulty in controlling or ending a hypnotic state that has been induced in the patient.

There is a commonly held belief that a person cannot be coerced into doing things that they would not normally do while under hypnosis. The hypnotherapist should take care not to give suggestions during hypnosis that are contrary to the patient's moral code.

Many religions do not condone the practice of hypnotherapy. Leaders of the Jehovah's Witnesses and Christian Science religions oppose the use of hypnotherapy and advise their members to avoid it completely, whether for entertainment or therapy. The Church of Jesus Christ of Latter-Day Saints approves it for medical purposes, but cautions members against allowing themselves to be hypnotized for entertainment or demonstration purposes.

In 1985, The AMA convened a commission that warned against using hypnotherapy to aid in recollection of events. The commission cited studies that showed the possibility of hypnotic recall resulting on confabulation or an artificial sense of certainty about the course of events. As a result, many states limit or prohibit testimony of hypnotized witnesses or victims.

Side effects

Experiments have been conducted to determine any side effects of hypnotherapy. Some subjects have reported side effects such as headache, stiff neck, drowsiness, cognitive distortion or confusion, **dizziness**, and anxiety. However, most of these effects cleared up within several hours of the hypnotherapy session.

Research and general acceptance

Research on the effectiveness of hypnotherapy on a variety of medical conditions is extensive. In one study, the use of hypnotherapy did not seem to alter the core symptoms in the treatment of attention-deficit hyperactivity disorder (**ADHD**); however, it did seem to be useful in managing the associated symptoms including sleep disturbances and tics.

Hypnotherapy is being studied in children who have common, chronic problems and to aid in relieving pain. Children are particularly good candidates for hypnotherapy because their lack of worldly experience enables them to move easily between the rational world and their imagination. Studies with children have shown responses to hypnotherapy ranging from diminished pain and anxiety during a number of medical procedures, a 50% range in reduction of symptoms or a complete resolution of a medical condition, and a reduction in use of anti-nausea medication and **vomiting** during **chemotherapy** for childhood cancers.

The use of hypnotherapy with cancer patients is another area being investigated. A meta-analysis of 116 studies showed very positive results of using hypnotherapy with cancer patients. Ninety-two percent showed a positive effect on depression; 93% showed a positive effect on physical well-being; 81% showed a positive effect on vomiting; and 92% showed a positive effect on pain.

Hypoactive sexual desire disorder

Definition

Hypoactive sexual desire disorder (HSDD) is a persistent or recurrent extreme aversion to or avoidance of genital sexual contact with a partner. HSDD is

WWW.BOOKBAZ.IR

also called sexual aversion, inhibited sexual desire, sexual apathy, or sexual anorexia.

Demographics

HSDD is one of the most common sexual disorders. However, the incidence of HSDD is difficult to estimate since as many as 40% of adults report a loss of sexual desire at some point in their lives. HSDD has traditionally been associated with women; however, 30% of women report that they have more interest in sex than their male partners. Estimates of the incidence of HSDD in both males and females range from 5–20%

Description

People with HSDD have a low level of sexual interest and desire that is manifested by the failure to initiate sexual activity or to respond to a partner's sexual overtures. Sexual desire normally fluctuates over the course of person's life. Often sexual desire is high at the beginning of a relationship and low as a relationship wanes. Illness can affect sexual desire, as can life changes such as **pregnancy** and **menopause** in women. According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM–IV–TR*), a diagnosis of HSDD requires a persistent or recurrent lack of sexual desire that causes marked distress or interpersonal instability. In the most extreme form of HSDD, the patient not only lacks sexual desire, but may find sex to be distasteful, repulsive, or revolting.

HSDD can take various forms:

- Primary HSDD is a condition in which the patient has never felt much sexual interest or desire.
- Secondary or acquired HSDD occurs in patients who formerly had normal sexual desires but no longer have any interest in sex.
- Generalized HSDD is a lack of sexual desire in all situations and with any partner.
- Situational or selective HSDD is an aversion directed at a specific partner or only under certain circumstances.

Risk factors

Because HSDD is caused by so many different physiological, psychological, and emotional factors, it is difficult to delineate risk factors. People who have experienced sexual **trauma** or were raised to have negative attitudes toward sex may be at greater risk for primary HSDD.

Causes and symptoms

The major symptom of HSDD is a lack of interest in sex, even under circumstances that are usually erotic, such as viewing pornography. Sexual activity is infrequent or nonexistent, causing distress or discord within relationships.

HSDD can result from physical, emotional, and/or psychological factors. Lifelong or primary HSDD can be a consequence of sexual trauma such as incest, **sexual abuse**, or rape. It can result from repressive family attitudes towards sex, which are sometimes reinforced by rigid religious training. HSDD occasionally occurs after initial attempts at sexual intercourse result in **pain** or sexual failure.

Acquired or situational HSDD in an adult is commonly associated with boredom in a sexual relationship. In such cases, as sexual frequency with the partner decreases, real or fantasized sexual desire for others remains normal or even increases. In addition to boredom, relationship issues that can cause situational HSDD include:

- lack of emotional connection with a sexual partner
- frequent quarrelling or unresolved conflicts with a partner
- poorly communicated sexual needs and preferences
- incompatible sexual interest, often because the unaffected partner is sexually demanding
- infidelity or other breach of trust

Psychological causes of HSDD include:

- a history of physical abuse
- depression
- anxiety
- stress
- poor body image
- low self–esteem

Physical causes of HSDD can include:

- hormonal changes due to pregnancy or breastfeeding
- estrogen deficiency due to female menopause
- low levels of the male sex hormone testosterone, which can also be deficient in postmenopausal women
- other hormonal abnormalities
- illnesses, such as cancer, arthritis, diabetes, high blood pressure, coronary artery disease, or neurological diseases
- surgery of the breasts or genital tract
- obesity
- drug or alcohol abuse

- impairment of sexual function, especially male erectile dysfunction or female vaginismus—an involuntary contraction or spasm of the lower vaginal muscles—which prevents vaginal penetration
- the inability to have an orgasm (aorgasmia)
- infertility
- fatigue

Various medications can cause HSDD including:

- selective serotonin reuptake inhibitors (SSRIs), including the antidepressants sertraline (Zoloft), paroxetine (Paxil), and fluoxetine (Prozac)
- blood pressure medications
- antihistamines
- birth control pills
- chemotherapy drugs
- HIV/AIDS drugs
- some hair–loss remedies

Painful intercourse (**dyspareunia**) is more common in women than in men, but can cause HSDD in either sex. Dyspareunia usually has a physical cause, such as an allergic reaction to a spermicidal preparation, lubricant, or condom. Female dyspareunia can be caused by **vaginismus**, urogenital trauma or infection, inflammatory conditions of the labia or vagina, or vaginal injuries. Male dyspareunia can result from infections of the prostate gland, urethra, or testes. Painful erections can be a consequence of Peyronie's disease, which is characterized by fibrotic changes in the shaft of the penis that prevent a normal erection.

Delayed sexual maturation is another potential cause of HSDD. In girls, delayed sexual maturation is characterized by a lack of breast enlargement by age 13 or by more than a five–year lapse between the initiation of breast growth and the onset of menstruation. Boys who have no testicular enlargement by 13.5 years of age or who experience more than a five–year lapse between initial and completed growth of the genitalia are considered to have delayed maturation. Delayed **puberty** can result from:

- familial constitutional disorders
- genetic defects such as Turner's syndrome in females or Klinefelter's syndrome in males
- central nervous system disorders, such as pituitary conditions that interfere with the secretion of gonadotropic hormones
- chronic illnesses such as diabetes mellitus, chronic renal failure, or cystic fibrosis

A rare but important cause of HSDD is a functional prolactin–secreting tumor of the pituitary gland, called a prolactinoma. Although prolactinomas are benign tumors, they can cause visual disturbances by enlarging and exerting pressure on the optic nerves. In females prolactinomas are associated with **galactorrhea** (**lactation** in the absence of pregnancy), **amenorrhea** (lack of a menstrual period), symptoms of estrogen deficiency, and dyspareunia. Males with prolactinomas typically have no interest in sex, although they can achieve an erection.

The pain that accompanies **priapism** can cause HSDD in males. Priapism is an erection lasting more than four hours and occurring in the absence of sexual stimulation. It is not associated with sexual excitement, and the erection does not subside after ejaculation. Although priapism can occur at any age, it is common in boys between the ages of 5 and 10 and in men between the ages of 20 and 50. Priapism in children is commonly associated with leukemia and **sickle cell disease** or occurs secondary to trauma. The most common cause in adults is the intrapenile injection of agents to correct **erectile dysfunction**. Priapism can also be caused by the use of psychotropic drugs, such as chlorpromazine and prazosin.

Sexual anhedonia is a rare type of male HSDD, in which the man experiences erection and ejaculation but derives no pleasure from orgasm. This is attributed to penile **anesthesia**, caused by psychogenic factors in a hysterical or obsessive person. Loss of tactile sensation in the penis is rarely due to physical factors unless there are associated anesthetized areas around the anus or scrotum.

Diagnosis

Examination

Diagnosis of HSDD will include a complete physical exam, a gynecological exam for women, a psychological evaluation, and medical and sexual histories, as well as an evaluation of prescribed and over–the–counter medications. Any physical causes of HSDD—such as abnormalities of the genitalia, prolactinoma, chronic renal disease, **diabetes mellitus**, a genetic disorder, or a family history of the disorder—must be identified.

Tests

Screening tests or questionnaires may be used to evaluate a patient's degree of sexual desire. Other testing may include:

- blood pressure
- estrogen levels in females, particularly in pre–and post–menopausal women
- testosterone levels in both males and females

KEY TERMS

Dyspareunia—Difficult or painful sexual intercourse.

Estrogen—Any of several naturally occurring or synthetic steroid hormones that promote the growth and maintenance of the female reproductive system.

Kegel exercises—Repetitive contractions to tone the pubococcygeal muscle of the pelvic floor for enhancing sexual response during intercourse or controlling incontinence.

Labia—The fatty folds of the vulva.

Priapism—A prolonged erection lasting more than four hours.

Prolactinoma—A benign (noncancerous) tumor of the pituitary gland that secretes the hormone prolactin.

Sexual anhedonia—The inability to experience sexual pleasure.

Testosterone—The primary male sex hormone, which is also produced at low levels in females.

Urethra—The tube that discharges urine from the bladder to the outside of the body.

Vaginismus—A painful spasmodic vaginal contraction.

- blood prolactin levels
- glucose tolerance to test for diabetes
- thyroid function
- iron deficiency

Procedures

Imaging techniques may be used in the diagnosis of physical causes of HSDD. Enlargement of the pituitary gland can be detected by **magnetic resonance imaging** (MRI) or computerized axial tomography (CAT or CT) scanning.

Treatment

Traditional

Any medical conditions underlying HSDD must be addressed; for example, genitourinary infections, poorly controlled diabetes, substance abuse, or suspect medications. Psychological causes of HSDD are addressed through behavioral or dynamic **psychotherapy**. HSDD often requires referral to a specialized counselor or sex therapist. Sexual anhedonia requires psychiatric referral unless there is evidence of **spinal cord injury** or **peripheral neuropathy**. Any other sexual disorders that can contribute to HSDD, such as erectile dysfunction, must be addressed. If the HSDD appears to be of a temporary or transient interpersonal nature, couples therapy may be beneficial. This requires the patience, support, and understanding of the sexual partner.

Drugs

In addition to any necessary adjustments in current medications, HSDD is sometimes treated with drugs:

- Systemic or local estrogen or estrogen/progesterone therapy can treat low hormone levels in menopausal women.
- A blood testosterone level of less than 300 nanograms (ng) per deciliter (dL) in males or 10 ng/dL in females may suggest testosterone replacement therapy. This is controversial for women and may have adverse side effects.
- Prescription testosterone creams or gels for women may improve sexual desire.
- Tricyclic antidepressants (TCAs) or monoamine oxidase inhibitors (MAOIs) may be used to treat depression or panic symptoms accompanying HSDD.
- Some studies have reported that non–depressed younger women with HSDD may respond favorably to sustained–release tablets of the antidepressant bupropion hydrochloride (Wellbutrin). Women have reported significant increases in frequency of sexual arousal, sexual fantasies, and desire to engage in sexual activities. Bupropion enhances the activity of the neurotransmitters norepinephrine and dopamine, which affect sexual desire.
- Dopamine–stimulating drugs also have been found to increase sexual desire in some men.
- Flibanserin, an antidepressant–type drug, is being marketed as a treatment for female HSDD, but is still seeking U.S. Food and Drug Administration (FDA) approval as of 2014.

Alternatives

Alternative remedies for HSDD include:

- vitamin E applied to the vagina

- Zestra genital massage oil, a proprietary blend of botanicals that includes borage seed and evening primrose oils, Angelica root, and vitamins C and E
- ArginMax, a nutritional supplement

Home remedies

Some sex therapists recommend a period of abstinence from genital sex and an increased emphasis on non–genital sex for the treatment of HSDD. Other methods for treating HSDD include:

- sexual lubricants
- experimenting with different sexual positions and settings, sex toys, and fantasies
- scheduling time for intimacy
- practicing open and honest communication with sexual partners
- regular aerobic exercise and strength–training to improve mood, body image, and libido
- stress management techniques
- for women, practicing Kegel (pelvic floor muscle) exercises for increasing pleasurable sexual sensations and libido

Prognosis

Prognosis depends primarily on the underlying causes of HSDD. For certain medical conditions the prognosis for the development or recovery of sexual interest is good. Examples include testosterone therapy for **hypogonadism** or appropriate treatment of a prolactin–secreting pituitary tumor. With certain genetic defects, such as Turner's and Klinefelter's syndromes, attainment of sexual function is impossible.

In general, psychotherapy has proved to be only minimally effective in the treatment of HSDD. The vast majority of HSDD cases are situational in nature, usually due to dissatisfaction or loss of interest in a sexual partner. In cases of marital discord, couples counseling by a healthcare professional trained in the field can be of significant assistance. However, cases in which both partners are dissatisfied often do not respond to such therapy and these situations frequently culminate in separation, finding new sexual partners, or divorce.

Prevention

Since the majority of HSDD cases are situational, they are difficult to predict or prevent. Open and honest communication between sexual partners is an important step.

Margaret Alic, PhD

Hypocalcemia

Definition

Hypocalcemia, a low blood **calcium** level, occurs when the level of total calcium in the blood falls below 8.5 mg/dL. The normal concentration of calcium in the blood serum is 8.7–10.4 mg/dL.

Description

Calcium is an important mineral for maintaining human health. It is not only a component of bones and teeth, but is also essential for normal blood clotting and necessary for normal muscle and nerve functions. The calcium ion (Ca^{2+}) has two positive charges. In bone, where 99% of calcium is found, calcium ions occur as a complex with phosphate to form crystals of calcium phosphate. In the bloodstream, calcium ions also occur in complexes, and here calcium is found combined with proteins and various nutrients. However, in the bloodstream, calcium also occurs in a free form. Normally, about 47% of the calcium in the blood plasma is free, 40% is bound to protein, and about 10% occurs in a complex form. Although all calcium in the bloodstream serves a useful purpose, only the concentration of free calcium ions has a direct influence on the functioning of nerves and muscles. For this reason, the measurement of the concentration of free calcium is more important in the diagnosis of disease than measuring the level of total calcium or complexed calcium. The level of total calcium in the blood serum is normally 8.7–10.4 mg/dL, while the level of free calcium is normally 4–5 mg/dL.

Causes and symptoms

Hypocalcemia can be caused by **hypoparathyroidism**, failure to produce 1,25-dihydroxyvitamin D, low levels of plasma magnesium, or by failure to get adequate amounts of calcium or **vitamin D** in the diet. Hypoparathyroidism involves the failure of the parathyroid gland to make parathyroid hormone. Parathyroid hormone controls and maintains plasma calcium levels. The hormone exerts its effect on the kidneys, where it triggers the synthesis of 1,25-dihydroxyvitamin D. Thus, hypocalcemia can be independently caused by damage to the parathyroid gland or to the kidneys. 1,25-Dihydroxyvitamin D stimulates the uptake of calcium from the diet and the mobilization of calcium from the bone. Bone mobilization is the natural process by which the body dissolves part of the bone in the skeleton in order to maintain or raise the levels of plasma calcium ions.

Low plasma magnesium levels (hypomagnesia) can result in hypocalcemia. Hypomagnesia can occur with **alcoholism** or with diseases characterized by an inability to properly absorb fat. Magnesium is required for parathyroid hormone to play its part in maintaining plasma calcium levels. For this reason, any disease that results in lowered plasma magnesium levels may also cause hypocalcemia.

Hypocalcemia may also result from the consumption of toxic levels of phosphate. Phosphate is a constituent of certain enema formulas. An enema is a solution used to cleanse the intestines via a device inserted into the rectum. Cases of hypocalcemia have been documented where people swallowed enema formulas, or where an enema has been administered to an infant.

Symptoms of severe hypocalcemia include numbness or tingling around the mouth or in the feet and hands, as well as **muscle spasms** in the face, feet, and hands. Hypocalcemia can result in depression, **memory loss**, or **hallucinations**. Long-term hypocalcemia can also result in dry skin and outbreaks of **psoriasis**. Chronic (lasting more than one year) and moderate hypocalcemia can result in **cataracts** (damage to the eyes).

Diagnosis

Tests

Hypocalcemia is diagnosed by acquiring a sample of blood and then measuring the calcium level in the blood. Hypocalcemia has several causes, and a full diagnosis requires assessment of the parathyroid gland, kidneys, and the plasma magnesium concentration. Other tests that may be ordered include magnesium level, phosphate level, and tests to determine the blood levels of other electrolytes. The physician may also order tests to determine renal function such as the blood urea nitrogen (BUN) and creatinine level blood tests. Blood testing for PTH level, albumin level, liver function, and coagulation capability may be done as well.

KEY TERMS

Albumin—A type of protein made by the liver and found in the blood.

Cardiac dysrhythmias—Abnormal heart rate, rhythm, or sequence of rhythms.

Ion—A particle that has a positive or negative charge.

The patient may be placed on cardiac monitoring to assess for cardiac dysrhythmias that can be triggered as a result of low calcium levels.

Treatment

The method chosen for treatment depends on the exact cause and on the severity of the hypocalcemia.

Drugs

Severe hypocalcemia requires intravenous replacement of calcium ions, usually in the form of calcium gluconate or calcium chloride. Oral calcium supplements are prescribed for long term treatment (non-emergency) of hypocalcemia. The oral supplements may take the form of calcium citrate, calcium carbonate, calcium chloride, or calcium gluconate. Hypocalcemia resulting from kidney failure is treated with injections of 1,25-dihydroxyvitamin D. Oral vitamin D supplements can increase gastrointestinal absorption of calcium. If hypocalcemia results from hypoparathyroidism, treatment may include oral calcium, 1,25-dihydroxyvitamin D, or other drugs. When low serum magnesium levels occur with hypocalcemia, the magnesium deficiency must be corrected to effectively treat the hypocalcemia.

Prognosis

The prognosis for correcting hypocalcemia is excellent. Damage to the eye that may result from chronic hypocalcemia cannot be reversed.

Prevention

The first, and most obvious, way to help prevent hypocalcemia is to ensure that adequate amounts of calcium and vitamin D are consumed each day, either in the diet or as supplements. The hypocalcemia that may occur with damage to the parathyroid gland or to the kidneys cannot be prevented. Hypocalcemia resulting from overuse of **enemas** can be prevented by reducing enema usage. Hypocalcemia resulting from magnesium deficiency tends to occur in chronic alcoholics, and this type of hypocalcemia can be prevented by reducing alcohol consumption and increasing the intake of healthy foods.

REVIEWED BY MELINDA GRANGER, RN, DNS, APRN, CNS

Hypochondriac *see* **Hypochondriasis**

Hypochondriasis

Definition

Hypochondriasis is a mental disorder characterized by excessive fear of or preoccupation with a serious illness, despite medical testing and reassurance to the contrary. It was formerly called hypochondriacal neurosis.

Description

Although hypochondriasis is often considered a disorder that primarily affects adults, it is now increasingly recognized in children and adolescents. In addition, hypochondriasis may develop in elderly people without previous histories of health-related fears. The disorder accounts for about 5% of psychiatric patients and is equally common in men and women.

Causes and symptoms

The causes of hypochondriasis are not precisely known. Children may have physical symptoms that resemble or mimic those of other family members. In adults, hypochondriasis may sometimes reflect a self-centered character structure or a wish to be taken care of by others; it may also have been copied from a parent's behavior. In elderly people, hypochondriasis may be associated with depression or grief. It may also involve biologically based hypersensitivity to internal stimuli.

WWW.BOOKBAZ.IR

Most hypochondriacs are worried about being physically sick, although some express fear of insanity. The symptoms reported can range from general descriptions of a specific illness to unusual complaints. In many instances the symptoms reflect intensified awareness of ordinary body functions, such as heartbeat, breathing, or stomach noises. It is important to understand that a hypochondriac's symptoms are not "in the head" in the sense of being delusional. The symptoms are real, but the patient misinterprets bodily functions and attributes them to a serious or even lethal cause.

Diagnosis

The diagnosis is often complicated by the patient's detailed understanding of symptoms and medical terminology from previous contacts with doctors. If a new doctor suspects hypochondriasis, he or she will usually order a complete medical workup in order to rule out physical disease.

Psychological evaluation is also necessary to rule out other disorders that involve feelings of **anxiety** or complaints of physical illness. These disorders include depression, **panic disorder**, and **schizophrenia** with somatic (physical) **delusions**. The following features are characteristic of hypochondriasis:

- The patient is not psychotic (out of touch with reality or hallucinating).
- The patient gets upset or blames the doctor when told there is "nothing wrong," or that there is a psychological basis for the problem.
- There is a correlation between episodes of hypochondriacal behavior and stressful periods in the patient's life.
- The behavior has lasted at least six months.

Evaluation of children and adolescents with hypochondriasis should include the possibility of **abuse** by family members.

Treatment

The goal of therapy is to help the patient (and family) live with the symptoms and to modify thinking and behavior that reinforces hypochondriacal symptoms. This treatment orientation is called supportive, as distinct from insight-oriented, because hypochondriacs usually resist psychological interpretations of their symptoms. Supportive treatment may include medications to relieve anxiety. Some clinicians look carefully for "masked" depression and treat with antidepressants.

Follow-up care includes regular physical checkups because about 30% of patients with hypochondriasis will eventually develop a serious physical illness. The physician also tries to prevent unnecessary medical testing and "doctor shopping" on the patient's part.

Prognosis

Between 33% and 55% of patients with hypochondriasis can expect significant improvement from the current methods of treatment.

Hypoesthesias *see* **Numbness and tingling**

Hypoglycemia

Definition

The condition called hypoglycemia is literally translated as low blood sugar. Hypoglycemia occurs when blood sugar (or blood glucose) concentrations fall below a level necessary to properly support the body's need for energy and stability throughout its cells.

Demographics

Attempts at quantifying the incidence of hypoglycemia is challenging, as many individuals do not regularly record, nor report the occurrence of this condition to their healthcare provider. It is thought to affect as many as 1 out of 1,000 people and can occur for a variety of reasons. Episodes of hypoglycemia occurring at night (nocturnal hypoglycemia) are commonly undetected by patients, and it is believed that about 6% of all deaths in diabetes are due to unrecognized nocturnal hypoglycemia.

Description

Carbohydrates are the main dietary source of the glucose that is manufactured in the liver and absorbed into the bloodstream to fuel the body's cells and organs. Glucose concentration is controlled

Hyperglycemia (high blood sugar symptoms)	Hypoglycemia (low blood sugar symptoms)
• Fatigue	• Shakiness
• High levels of sugar in urine	• Dizziness
• Frequent urination	• Sweating
• Increased thirst	• Hunger
• Hunger	• Headache
• Blurry vision	• Sudden moodiness or behavior changes
• Impotence (male)	• Clumsy or jerkey movements
• Unintentional weight loss	• Seizure
• Tingling or numbness in hands or feet	• Difficulty paying attention, or confusion
	• Tingling sensations around the mouth

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

by hormones, primarily insulin and glucagon. Glucose concentration also is controlled by epinephrine (adrenalin) and norepinephrine, as well as growth hormone. If these regulators are not working properly, levels of blood sugar can become either excessive (as in hyperglycemia) or inadequate (as in hypoglycemia). If a person has a blood sugar level of 50 mg/dL or less, he or she is considered hypoglycemic, although glucose levels vary widely from one person to another.

Hypoglycemia can occur in several ways.

Drug-induced hypoglycemia

Drug-induced hypoglycemia, a complication of diabetes, is the most commonly seen and most dangerous form of hypoglycemia.

Hypoglycemia occurs most often in diabetics who must inject insulin periodically to lower their blood sugar. While other diabetics also are vulnerable to low blood sugar episodes, they have a lower risk of a serious outcome than insulin-dependent diabetics. Unless recognized and treated immediately, severe hypoglycemia in the insulin-dependent diabetic can lead to generalized convulsions followed by **amnesia** and unconsciousness. Death, though rare, is a possible outcome.

In insulin-dependent diabetics, hypoglycemia known as an insulin reaction or insulin **shock** can be caused by several factors. These include overmedicating with manufactured insulin, missing or delaying a meal, eating too little food for the amount of insulin taken, exercising too strenuously, drinking too much alcohol, or any combination of these factors.

Reactive hypoglycemia

Reactive hypoglycemia (also called postprandial hypoglycemia) occurs about 2–4 hours after eating a meal. A number of reasons for this reaction have been proposed, but no single cause has been identified.

In some cases, this form of hypoglycemia appears to be associated with malfunctions or diseases of the liver, pituitary, adrenals, liver, or pancreas. These conditions are unrelated to diabetes. Children intolerant of a natural sugar (fructose) or who have inherited defects that affect digestion also may experience hypoglycemic attacks. Some children with a negative reaction to **aspirin** also experience reactive hypoglycemia. It sometimes occurs among people with an intolerance to the sugar found in milk (galactose), and it also often begins before diabetes strikes later in life.

Fasting hypoglycemia

Fasting hypoglycemia sometimes occurs after long periods without food, but it also happens occasionally following strenuous **exercise**, such as running in a marathon.

Other factors sometimes associated with hypoglycemia include:

- pregnancy
- a weakened immune system
- a poor diet high in simple carbohydrates
- prolonged use of drugs, including antibiotics
- chronic physical or mental stress
- heartbeat irregularities (arrhythmias)
- allergies
- breast cancer

WWW.BOOKBAZ.IR

- high blood pressure treated with beta-blocker medications (after strenuous exercise)
- upper gastrointestinal tract surgery

Causes and symptoms

When carbohydrates are eaten, they are converted to glucose that goes into the bloodstream and is distributed throughout the body. Simultaneously, a combination of chemicals that regulate how our body's cells absorb that sugar is released from the liver, pancreas, and adrenal glands. These chemical regulators include insulin, glucagon, epinephrine (adrenalin), and norepinephrine. The mixture of these regulators released following digestion of carbohydrates is never the same, since the amount of carbohydrates that are eaten is never the same.

Interactions among the regulators are complicated. Any abnormalities in the effectiveness of any one of the regulators can reduce or increase the body's absorption of glucose. Gastrointestinal enzymes such as amylase and lactase that break down carbohydrates may not be functioning properly. These abnormalities may produce hyperglycemia or hypoglycemia and can be detected when the level of glucose in the blood is measured.

Cell sensitivity to these regulators can be changed in many ways. Over time, a person's **stress** level, exercise patterns, advancing age, and dietary habits influence cellular sensitivity. For example, a diet consistently overly rich in carbohydrates increases insulin requirements over time. Eventually, cells can become less receptive to the effects of the regulating chemicals, which can lead to glucose intolerance.

Diet is both a major factor in producing hypoglycemia as well as the primary method for controlling it. **Diets** typical of Western cultures contain excess carbohydrates, especially in the form of simple carbohydrates such as sweeteners, which are more easily converted to sugar. In developing parts of the world, the typical diet contains even higher levels of carbohydrates. Fewer dairy products and meats are eaten, and grains, vegetables, and fruits are consumed. This dietary trend is balanced, however, since people in these cultures eat small meals and usually use carbohydrates efficiently through physical labor.

Early symptoms of severe hypoglycemia, particularly in the drug-induced type of hypoglycemia, resemble an extreme shock reaction. Symptoms include:

- cold and pale skin
- numbness around the mouth
- apprehension
- heart palpitations
- emotional outbursts
- hand tremors
- mental cloudiness
- dilated pupils
- sweating
- fainting

Mild attacks are more common in reactive hypoglycemia and are characterized by extreme tiredness. Patients first lose their alertness, then their muscle strength and coordination. Thinking grows fuzzy, and finally the patient becomes so tired that he or she becomes "zombie-like," awake but not functioning. Sometimes the patient will actually fall asleep. Unplanned naps are typical of the chronic hypoglycemic patient, particularly following meals.

Additional symptoms of reactive hypoglycemia include headaches, double vision, staggering or inability to walk, a craving for salt and/or sweets, abdominal distress, premenstrual tension, chronic **colitis**, **allergies**, ringing in the ears, unusual patterns in the frequency of urination, skin eruptions and inflammations, **pain** in the neck and shoulder muscles, memory problems, and sudden and excessive sweating.

Unfortunately, a number of these symptoms mimic those of other conditions. For example, the depression, **insomnia**, irritability, lack of concentration, crying spells, **phobias**, forgetfulness, confusion, unsocial behavior, and suicidal tendencies commonly seen in nervous system and psychiatric disorders also may be hypoglycemic symptoms. It is very important that anyone with symptoms that may suggest reactive hypoglycemia see a doctor.

Because all of its possible symptoms are not likely to be seen in any one person at a specific time, diagnosing hypoglycemia can be difficult. One or more of its many symptoms may be due to another illness. Symptoms may persist in a variety of forms for long periods of time. Symptoms also can change over time within the same person. Some of the factors that can influence symptoms include physical or mental activities, physical or mental state, the amount of time passed since the last meal, the amount and quality of sleep, and exercise patterns.

Diagnosis

Drug-induced hypoglycemia

Once diabetes is diagnosed, the patient monitors his or her blood sugar level with a portable machine called a glucometer. The diabetic places a small blood sample on a test strip that the machine can read. If the test reveals that the blood sugar level is too low, the

diabetic can make a correction by eating or drinking an additional carbohydrate.

Reactive hypoglycemia

Reactive hypoglycemia only can be diagnosed by a doctor. Symptoms usually improve after the patient has gone on an appropriate diet. Reactive hypoglycemia was diagnosed more frequently in the late twentieth century than at the end of the first decade of the twenty-first century. Studies have shown that most people with its symptoms test normal for blood sugar, leading many doctors to suggest that actual cases of reactive hypoglycemia are quite rare. Some doctors think that people with hypoglycemic symptoms may be particularly sensitive to the body's normal postmeal release of the hormone epinephrine, or are actually suffering from some other physical or mental problem. Other doctors believe reactive hypoglycemia actually is the early onset of diabetes that occurs after a number of years. There continues to be disagreement about the cause of reactive hypoglycemia.

A common test to diagnose hypoglycemia is the extended oral glucose tolerance test. Following an overnight fast, a concentrated solution of glucose is drunk and blood samples are taken hourly for five to six hours. Though this test remains helpful in early identification of diabetes, its use in diagnosing chronic reactive hypoglycemia has lost favor because it can trigger hypoglycemic symptoms in people with otherwise normal glucose readings. Some doctors now recommend that blood sugar be tested at the actual time a person experiences hypoglycemic symptoms.

Treatment

Treatment of the immediate symptoms of hypoglycemia can include eating sugar. For example, a patient can eat a piece of candy, drink milk, or drink fruit juice. Glucose tablets can be used by patients, especially those who are diabetic. Effective treatment of hypoglycemia over time requires the patient to follow a modified diet. Patients usually are encouraged to eat small, but frequent, meals throughout the day, avoiding excess simple sugars (including alcohol), fats, and fruit drinks. Those patients with severe hypoglycemia may require fast-acting glucagon injections that can stabilize their blood sugar within approximately 15 minutes.

Alternatives

A holistic approach to reactive hypoglycemia is based on the belief that a number of factors may create the condition. Among them are heredity, the effects of other illnesses, emotional stress, too much or too little exercise, bad lighting, poor diet, and environmental pollution. Therefore, a number of alternative methods have been proposed as useful in treating the condition. **Homeopathy**, **acupuncture**, and **applied kinesiology**, for example, have been used, as have herbal remedies. One of the herbal remedies commonly suggested for hypoglycemia is a decoction (an extract made by boiling) of gentian (*Gentiana lutea*). It should be drunk warm 15–30 minutes before a meal. Gentian is believed to help stimulate the endocrine (hormone-producing) glands.

In addition to dietary modifications, people with hypoglycemia may benefit from supplementing their diet with chromium, which is believed to help improve blood sugar levels. Chromium is found in whole grain breads and cereals, cheese, molasses, lean meats, and brewer's yeast. Hypoglycemics should avoid alcohol, **caffeine**, and cigarette smoke, since these substances can cause significant swings in blood sugar levels.

Prevention

Drug-induced hypoglycemia

Preventing hypoglycemic insulin reactions in diabetics requires taking glucose readings through frequent blood sampling. Insulin then can be regulated based on those readings. Continuous glucose monitoring sensors have been developed to help diabetics remain more aware of possible hypoglycemic episodes. These monitors even can check for episodes while the patient sleeps, when many will experience severe hypoglycemia but not know it. Those who do not pay attention to severe hypoglycemia events or who have had previous severe hypoglycemia are the most likely to have future severe hypoglycemia. An audible alert can let the patient know immediately that he or she needs to take care of his or her blood sugar level. Continuous monitoring has proved particularly helpful in pediatric patients with Type 1 diabetes.

Maintaining proper diet also is a factor. Programmable insulin pumps implanted under the skin have proven useful in reducing the incidence of hypoglycemic episodes for insulin-dependent diabetics. Clinical studies continue to seek additional ways to control diabetes and drug-induced hypoglycemia. Tests of a substance called pramlintide indicate that it may help improve glycemic control in diabetics.

Reactive hypoglycemia

The onset of reactive hypoglycemia can be avoided or at least delayed by following the same kind of diet used to control it. While not as restrictive

WWW.BOOKBAZ.IR

as the diet diabetics must follow to keep tight control over their disease, it is quite similar.

There are a variety of diet recommendations for the reactive hypoglycemic. Patients should:

- avoid overeating
- never skip breakfast
- include protein in all meals and snacks, preferably from sources low in fat, such as the white meat of chicken or turkey, most fish, soy products, or skim milk
- restrict intake of fats (particularly saturated fats, such as animal fats), and avoiding refined sugars and processed foods
- be aware of the differences between some vegetables, such as potatoes and carrots. These vegetables have a higher sugar content than others (like squash and broccoli). Patients should be aware of these differences and note any reactions they have to them.
- be aware of differences found in grain products. White flour is a carbohydrate that is rapidly absorbed into the bloodstream, while oats take much longer to break down in the body.
- keep a food diary. Until the diet is stabilized, a patient should note what and how much he/she eats and drinks at every meal. If symptoms appear following a meal or snack, patients should note them and look for patterns.
- eat fresh fruits, but restrict the amount they eat at one time. Patients should remember to eat a source of protein whenever they eat high sources of carbohydrate like fruit. Apples make particularly good snacks because, of all fruits, the carbohydrate in apples is digested most slowly.
- follow a diet that is high in fiber. Fruit is a good source of fiber, as are oatmeal and oat bran. Fiber slows the buildup of sugar in the blood during digestion.

A doctor can recommend a proper diet, and there are many cookbooks available for diabetics. Recipes found in such books are equally effective in helping to control hypoglycemia.

Prognosis

Like diabetes, there is no cure for reactive hypoglycemia, only ways to control it. While some chronic cases will continue through life (rarely is there complete remission of the condition), others will develop into type II (age onset) diabetes. Hypoglycemia appears to have a higher-than-average incidence in families where there has been a history of hypoglycemia or diabetes among their members, but whether hypoglycemia is a controllable warning of oncoming diabetes has not yet been determined by clinical research.

A condition known as hypoglycemia unawareness can develop in those who do not control their blood glucose, particularly in people with Type 1 diabetes. These people may lose notice of the automatic warning symptoms of hypoglycemia that normally occur as their bodies become so used to frequent periods of hypoglycemia. It is not a permanent event, but can be treated by careful avoidance of hypoglycemia for about two weeks.

Hypogonadism

Definition

Hypogonadism is the condition more prevalent in males in which the production of sex hormones and germ cells are inadequate.

Description

Gonads are the organs of sexual differentiation—in the female, they are ovaries; in the male, the testes. Along with producing eggs and sperm, they produce sex hormones that generate all the differences between men and women. If they produce too little sex hormone, then either the growth of the sexual organs or their function is impaired.

The gonads are not independent in their function, however. They are closely controlled by the pituitary gland. The pituitary hormones are the same for males and females, but the gonadal hormones are different. Men produce mostly androgens, and women produce mostly estrogens. These two hormones regulate the development of the embryo, determining whether it is a male or a female. They also direct the adolescent maturation of sex organs into their adult form. Further, they sustain those organs and their function throughout the reproductive years. The effects of estrogen reach beyond that to sustain bone strength and protect the cardiovascular system from degenerative disease.

Hormones can be inadequate during or after each stage of development—embryonic and adolescent. During each stage, inadequate hormone stimulation will prevent normal development. After each stage, a decrease in hormone stimulation will result in failed function and perhaps some shrinkage. The organs affected principally by sex hormones are the male and female genitals, both internal and external, and the female breasts. Body hair, fat deposition, bone and muscle growth, and some brain functions are also influenced.

Causes and symptoms

Sex is determined at the moment of conception by sex chromosomes. Females have two X chromosomes, while males have one X and one Y chromosome. If male sperm with a Y chromosome fertilizes an egg, the baby will be male. This is true throughout the animal kingdom. Genetic defects sometimes result in changes in the chromosomes. If sex chromosomes are involved, there is a change in the development of sexual characteristics.

Female is the default sex of the embryo, so most of the sex organ deficits at birth occur in boys. Some, but not all, are due to inadequate androgen stimulation. The penis may be small, the testicles undescended (cryptorchidism), or various degrees of "feminization" of the genitals may be present.

After birth, sexual development does not occur until **puberty**. Hypogonadism most often shows up as an abnormality in boys during puberty. Again, not every defect is due to inadequate hormones. Some are due to too much of the wrong ones. Kallmann's syndrome is a birth defect in the brain that prevents release of hormones and appears as failure of male puberty. Some boys have adequate amounts of androgen in their system but fail to respond to them, a condition known as androgen resistance.

Female problems in puberty are not caused by too little estrogen. Even female reproductive problems are rarely related to a simple lack of hormones, but rather to complex cycling rhythms gone wrong. All the problems with too little hormone happen during **menopause**, which is a normal hypogonadism.

A number of adverse events can damage the gonads and result in decreased hormone levels. The childhood disease **mumps**, if acquired after puberty, can infect and destroy the testicles—a disease called viral **orchitis**. Ionizing radiation and **chemotherapy**, **trauma**, several drugs (spironolactone, a diuretic and ketoconazole, an antifungal agent), alcohol, **marijuana**, heroin, **methadone**, and environmental toxins can all damage testicles and decrease their hormone production. Severe diseases in the liver or kidneys, certain infections, sickle cell anemia, and some cancers also affect gonads. To treat some male cancers, it is necessary to remove the testicles, thereby preventing the androgens from stimulating cancer growth. This procedure, called castration or *orchiectomy*, removes androgen stimulation from the whole body.

For several reasons the pituitary can fail. It happens rarely after **pregnancy**. It used to be removed to treat advanced breast or **prostate cancer**. Sometimes the pituitary develops a tumor that destroys it. Failure of the pituitary is called **hypopituitarism**, it leaves the gonads with no stimulation to produce hormones.

Besides the tissue changes generated by hormone stimulation, the only other symptoms relate to sexual desire and function. Libido is enhanced by testosterone, and male sexual performance requires androgens. The role of female hormones in female sexual activity is less clear, although hormones strengthen tissues and promote healthy secretions, facilitating sexual activity.

WWW.BOOKBAZ.IR

Diagnosis

There are accurate blood tests for most of the hormones in the body, including those from the pituitary and even some from the hypothalamus. Chromosomes can be analyzed, and gonads can be, but rarely are, biopsied.

Treatment

Replacement of missing body chemicals is much easier than suppressing excesses. Estrogen replacement is recommended for nearly all women after menopause for its many beneficial effects. Estrogen can be taken by mouth, injection, or skin patch. It is strongly recommended that the other female hormone, progesterone, be taken as well, because it prevents overgrowth of uterine lining and uterine cancer. Testosterone replacement is available for males who are deficient.

Hypokalemia

Definition

Hypokalemia is a condition of below-normal levels of potassium in the blood serum. Potassium, a necessary electrolyte, facilitates nerve impulse conduction and the contraction of skeletal and smooth muscles, including the heart. It also facilitates cell membrane function and proper enzyme activity. Levels must be kept in a proper (homeostatic) balance for the maintenance of health. The normal concentration of potassium in the serum is in the range of 3.5–5.0 mEq/L. Hypokalemia means serum or plasma levels of potassium ions that fall below 3.5 mEq/L. Moderate hypokalemia may be defined as serum potassium between 2.5 and 3.0 mEq/L, while severe hypokalemia is defined as serum potassium under 2.5 mEq/L. (Potassium concentrations are often expressed in units of milliequivalents per liter [mEq/L], rather than in units of millimolarity [mM], however, both units are identical and mean the same thing when applied to concentrations of potassium ions.)

Hypokalemia can result from two general causes: either from an overall depletion in the body's potassium or from excessive uptake of potassium by muscle from surrounding fluids.

Description

A normal adult weighing about 154 lb. (70 kg) has about 3.6 moles of potassium ions in his body. Most of this potassium (about 98%) occurs inside various cells and organs, where normal concentrations are about 150 mEq/L. Blood serum concentrations are much lower—only about 0.4% of the body's potassium is found in blood serum. Hypokalemia can be caused by the sudden uptake of potassium ions from the bloodstream by muscle or other organs or by an overall depletion of the body's potassium. Hypokalemia due to overall depletion tends to be a chronic phenomenon, while hypokalemia due to a shift in location tends to be a temporary disorder.

Causes and symptoms

Hypokalemia is most commonly caused by the use of **diuretics**. Diuretics are drugs that increase the excretion of water and salts in the urine. Diuretics are used to treat a number of medical conditions, including **hypertension** (high blood pressure), **congestive heart failure**, **liver disease**, and **kidney disease**. Diuretic treatment can have the side effect of producing hypokalemia. In fact, the most common cause of hypokalemia in the elderly is the use of diuretics. The use of furosemide and thiazide, two commonly used diuretic drugs, can lead to hypokalemia. In contrast, spironolactone and triamterene are diuretics that do not provoke hypokalemia.

Other common causes of hypokalemia are excessive **diarrhea** or **vomiting**. Diarrhea and vomiting can be produced by infections of the gastrointestinal tract. Caused by a variety of organisms, including bacteria, protozoa, and viruses, diarrhea is a major world health problem. It is responsible for about a quarter of the 10 million infant deaths that occur each year. Although nearly all of these deaths occur in the poorer parts of Asia and Africa, diarrheal diseases are a leading cause of infant death in the United States. Diarrhea results in various abnormalities, such as **dehydration** (loss in body water), **hyponatremia** (low **sodium** level in the blood), and hypokalemia.

Because of the need for potassium to control muscle action, hypokalemia can cause the heart to stop beating. Young infants are especially at risk for death from this cause, especially where severe diarrhea continues for two weeks or longer. Diarrhea due to

laxative abuse is an occasional cause of hypokalemia in the adolescent or adult. Enema abuse is a related cause of hypokalemia. Laxative abuse is difficult to diagnose and treat, because patients usually deny the practice. Up to 20% of persons complaining of chronic diarrhea practice laxative abuse. Laxative abuse is often part of **eating disorders**, such as **anorexia nervosa** or **bulimia nervosa**. Hypokalemia that occurs with these eating disorders may be life-threatening.

The potassium loss that accompanies vomiting is only partly due to loss of potassium from the vomit. Vomiting also has the effect of provoking an increase in potassium loss in the urine. It expels acid from the mouth, and this loss of acid results in alkalization of the blood. (Alkalization of the blood means that the pH of the blood increases slightly.) An increased blood pH has a direct effect on the kidneys. Alkaline blood provokes the kidneys to release excessive amounts of potassium in the urine. Severe and continual vomiting can cause excessive losses of potassium from the body and hypokalemia.

A third general cause of hypokalemia is prolonged **fasting** and **starvation**. In most people, after three weeks of fasting, blood serum potassium levels decline to below 3.0 mEq/L and result in severe hypokalemia. In some persons, serum potassium may be naturally maintained at about 3.0 mEq/L, even after 100 days of fasting. During fasting, muscle is naturally broken down, and the muscle protein is converted to sugar (glucose) to supply to the brain the glucose that is essential for its functioning. Other organs are able to survive with a mixed supply of fat and glucose. The potassium within the muscle cell is released during the gradual process of muscle breakdown that occurs with starvation, and this can help counteract the trend to hypokalemia during starvation. Eating an unbalanced diet does not cause hypokalemia because most foods, such as fruits (especially bananas, oranges, and melons), vegetables, meat, milk, and cheese, are good sources of potassium. Only foods such as butter, margarine, vegetable oil, soda water, jelly beans, and hard candies are extremely poor in potassium.

Alcoholism occasionally results in hypokalemia. About one-half of alcoholics hospitalized for withdrawal symptoms experience hypokalemia. The hypokalemia of alcoholics occurs for a variety of reasons, usually poor **nutrition**, vomiting, and diarrhea. Hypokalemia can also be caused by **hyperaldosteronism**; Cushing's syndrome; hereditary kidney defects, such as Liddle's syndrome, Bartter's syndrome, and Franconi's syndrome; and eating too much licorice.

KEY TERMS

Cardiac arrhythmia—An abnormality in the rate or rhythm of the heartbeat.

Ileus—A blockage of the intestine. Ileus caused by hypokalemia is often termed paralytic ileus because peristalsis, the rhythmic contractions within the bowel that propels digested food through the intestinal tract, ceases.

Symptoms

Mild hypokalemia usually results in no symptoms, while moderate hypokalemia results in confusion, disorientation, weakness, and discomfort of muscles. On occasion, moderate hypokalemia causes cramps during **exercise**. Another symptom of moderate hypokalemia is a discomfort in the legs that is experienced while sitting still. The patient may experience an annoying feeling that can be relieved by shifting the positions of the legs or by stomping the feet on the floor. Severe hypokalemia results in extreme weakness of the body and, on occasion, in **paralysis**. The paralysis that occurs is "flaccid paralysis," or limpness. Paralysis of the muscles of the lungs results in death. Other signs of severe hypokalemia include low blood pressure (hypokalemia), low heart rate, and signs of an **ileus**. Another dangerous result of severe hypokalemia is abnormal heart beat (arrhythmia) that can lead to death from cardiac arrest (cessation of heart beat).

Diagnosis

Hypokalemia can be measured by acquiring a sample of blood and by then measuring the concentration of potassium ions in the blood. Since hypokalemia results in abnormalities in heart rhythm, an electrocardiogram is usually used in the diagnosis of hypokalemia. The diagnosis of the cause of hypokalemia can be done by measuring the potassium content of the urine. Where urinary potassium is under 25 mEq/L per day, it means that the patient has experienced excessive losses of potassium due to diarrhea. The urinary potassium test is useful in cases where the patient is denying the practice of laxative or enema abuse. In contrast, where hypokalemia is due to the use of diuretic drugs, the content of potassium in the urine will be high—over 40 mEq/L per day.

Treatment

In emergency situations, when severe hypokalemia is suspected, the patient should be placed on a cardiac monitor, and respiratory status should be

WWW.BOOKBAZ.IR

assessed. If laboratory test results show potassium levels below 2.5 mEq/L, intravenous potassium should be given. Patients with severe hypokalemia may receive intravenous potassium in the emergency department or may need to be admitted to an inpatient facility to continue replacement therapy under close observation.

In less urgent cases, potassium can be given orally in pill form. Oral potassium chloride (KCl) is the safest and most effective treatment for hypokalemia. Generally, the consumption of 40–80 mEq/L of KCl per day is sufficient to correct the hypokalemia that results from diuretic therapy. For many people taking diuretics, potassium supplements are not necessary as long as they eat a balanced diet containing foods rich in potassium.

Prognosis

The prognosis for correcting hypokalemia is excellent. In emergency situations where potassium is administered intravenously, the physician must be careful not to give too much potassium. The administration of potassium at high levels, or at a high rate, can lead to abnormally high levels of serum potassium, which can result in cardiac **arrhythmias**.

Prevention

Hypokalemia is not a concern for healthy persons, since potassium is present in a great variety of foods. For patients taking diuretics, the American Dietetic Association recommends use of a high potassium diet. However, if hypokalemia has already occurred, use of the high potassium diet alone may not reverse hypokalemia. Useful components of a high potassium diet include bananas, tomatoes, cantaloupes, figs, raisins, kidney beans, potatoes, and milk.

Hypolipoproteinemia

Definition

Hypolipoproteinemia (or hypolipidemia) is the lack of fat in the blood.

Description

Although quite rare, hypolipoproteinemia is a serious condition. Blood absorbs fat from food in the intestine and transports it as a combined package with proteins and other chemicals like **cholesterol**. Much of the fat goes straight into the liver for processing. The cholesterol, a waste product, ends up in the bile. The proteins act as vessels, carrying the other chemicals around. These packages of fat, cholesterol, and proteins are called lipoproteins.

Causes and symptoms

Low blood fats can be the result of several diseases, or they can be a primary genetic disease with other associated abnormalities.

- Malnutrition is a lack of food, including fats, in the diet.
- Malabsorption is the inability of the bowel to absorb food, causing malnutrition.
- Anemia (too few red blood cells) and hyperthyroidism (too much thyroid hormone) also reduce blood fats.
- Rare genetic conditions called hypobetalipoproteinemia and abetalipoproteinemia cause malabsorption plus nerve, eye, and skin problems in early childhood.
- Tangier disease, causes only the cholesterol to be low. It also produces nerve and eye problems in children.

Symptoms are associated more closely with the cause rather than the actual low blood fats.

Diagnosis

Blood studies of the various fat particles help identify both the low and high fat diseases. These tests are often done after an overnight fast to prevent interference from fat just being absorbed from food. Fats and proteins are grouped together and described by density—high-density lipoproteins (HDL), low-density lipoproteins (LDL), and very low-density lipoproteins (VLDL). There are also much bigger particles called chylomicrons. Each contain different proportions of cholesterol, fats, and protein.

Treatment

Supplemental **vitamin E** helps children with betalipoprotein deficiencies. There is no known treatment for Tangier disease. Treatment of the causes of the other forms of low blood fats reverses the condition.

Hypomagnesemia *see* **Magnesium imbalance**

Hyponatremia

Definition

The normal concentration of **sodium** in the blood plasma is 136–145 mEq/L. Hyponatremia, the most commonly observed electrolyte imbalance, occurs when sodium falls below 130 mEq/L. Plasma sodium levels of 125 mEq/L or less are dangerous and can result in seizures and **coma**.

Description

Sodium is an atom, or ion, that carries a single positive charge. The sodium ion may be abbreviated as Na^+ or as simply Na. Sodium can occur as a salt in a crystalline solid. Sodium chloride (NaCl), sodium phosphate (Na_2HPO_4), and sodium bicarbonate ($NaHCO_3$) are commonly occurring salts. These salts can be dissolved in water or in juices of various foods. Dissolving involves the complete separation of ions, such as sodium and chloride, in common table salt (NaCl).

About 40% of the body's sodium is contained in bone. Approximately 2–5% occurs within organs and cells and the remaining 55% is in blood plasma and other extracellular fluids. The amount of sodium in blood plasma is typically 140 mEq/L, a much higher amount than is found in intracellular sodium (about 5 mEq/L). This asymmetric distribution of sodium ions is essential for human life. It makes possible proper nerve conduction, the passage of various nutrients into cells, and the maintenance of blood pressure.

The body continually regulates its handling of sodium. When dietary sodium is too high or low, the intestines and kidneys respond to adjust concentrations to normal. During the course of a day, the intestines absorb dietary sodium while the kidneys excrete a nearly equal amount of sodium into the urine. If a low sodium diet is consumed, the intestines increase their efficiency of sodium absorption, and the kidneys reduce its release into urine.

The concentration of sodium in the blood plasma depends on two things: 1) the total amount of sodium and, 2) water in arteries, veins, and capillaries (the circulatory system). The body uses separate mechanisms to regulate sodium and water, but they work together to correct blood pressure when it is too high or too low. Too low a concentration of sodium, or hyponatremia, can be corrected either by increasing sodium or by decreasing body water. The existence of separate mechanisms that regulate sodium concentration account for the fact that there are numerous diseases that can cause hyponatremia, including diseases of the kidney, pituitary gland, and hypothalamus.

Causes and symptoms

Hyponatremia can be caused by abnormal consumption or excretion of dietary sodium or water and by diseases that impair the body's ability to regulate them. Maintenance of a low salt diet for many months or excessive sweat loss during a race on a hot day can present a challenge to the body to conserve adequate sodium levels. While these conditions alone are not likely to cause hyponatremia, it can occur under special circumstances. For example, hyponatremia often occurs in patients taking diuretic drugs who maintain a low sodium diet. This is especially of concern in elderly patients, who have a reduced ability to regulate the concentrations of various nutrients in the bloodstream. Diuretic drugs that frequently cause hyponatremia include furosemide (Lasix), bumetanide (Bumex), and most commonly, the thiazide **diuretics**. Diuretics enhance the excretion of sodium into the urine, with the goal of correcting high blood pressure; too much sodium excretion can result in hyponatremia. Usually only mild hyponatremia occurs in patients taking diuretics, but when combined with a low sodium diet or with the excessive drinking of water, severe hyponatremia can develop.

Severe and prolonged **diarrhea** can cause hyponatremia. Severe diarrhea, causing the daily output of 8–10 L of fluid from the large intestines, results in the loss of large amounts of water, sodium, and various nutrients. Some diarrheal diseases release particularly large quantities of sodium and are most likely to cause hyponatremia.

WWW.BOOKBAZ.IR

Drinking excess water sometimes causes hyponatremia because the absorption of water into the bloodstream can dilute the sodium in the blood. This cause of hyponatremia is rare, but has been found in psychotic patients who compulsively drink more than 5 gal. (20 L) of water per day. Excessive drinking of beer, which is mainly water and low in sodium, can also produce hyponatremia when combined with a poor diet.

Marathon running, under certain conditions, leads to hyponatremia. Races of 25–50 mi. (40–80 km) can result in the loss of great quantities (2–2.6 gal.; 8–10 L) of sweat, which contains both sodium and water. Studies show that about 30% of marathon runners experience mild hyponatremia during a race. Runners who consume only pure water during a race can develop severe hyponatremia because the drinking water dilutes the sodium in the bloodstream. Such runners may experience neurological disorders as a result of the severe hyponatremia and require emergency treatment.

Hyponatremia also develops from disorders in organs that control the body's regulation of sodium or water. The adrenal gland secretes a hormone called aldosterone that travels to the kidney, where it causes the kidney to retain sodium by not excreting it into the urine. Addison's disease causes hyponatremia as a result of low levels of aldosterone due to damage to the adrenal gland. The hypothalamus and pituitary gland are involved in sodium regulation by making and releasing vasopressin, known as anti-diuretic hormone, into the bloodstream. Like aldosterone, vasopressin acts in the kidney, but it causes it to reduce the amount of water released into urine. With more vasopressin production, the body conserves water, resulting in a lower concentration of plasma sodium. Certain types of cancer cells produce vasopressin, leading to hyponatremia.

Hyponatremia can be acute, developing over 48 hours or less, or chronic, taking days or sometimes weeks to develop. Patient symptoms are often milder if the hyponatremia occurs over time because the body, particularly the brain, has time to compensate for the lower serum (blood) sodium concentration. When hyponatremia occurs rapidly, there is less time for the brain to adjust to the lowered sodium level and clinical manifestations related to cerebral **edema** are common. If the cerebral edema is severe enough, the result may be herniation of the brainstem and death. Rapid identification and treatment of the hyponatremic state is critical in averting these serious complications.

Symptoms of moderate hyponatremia include tiredness, disorientation, **headache**, **muscle cramps**, and nausea. Severe hyponatremia can lead to seizures and coma. These neurological symptoms are thought to result from the movement of water into brain cells, causing them to swell and disrupt their functioning (cerebral edema).

KEY TERMS

Cerebral edema—Movement of water into brain cells causing the cells to swell, which disrupts normal functioning of the cells.

Diuretic—Medication that enhances the functioning of the kidney. Typically results in increased elimination of urine from the body.

Plasma—Clear, yellow- or straw-colored fluid that is the liquid component of blood and lymphatic fluid.

In most cases of hyponatremia, doctors are primarily concerned with discovering the underlying disease causing the decline in plasma sodium levels. Death that occurs during hyponatremia is usually due to other features of the disease rather than to hyponatremia itself.

Diagnosis

Tests

Hyponatremia is diagnosed by acquiring a blood sample and then measuring the concentration of sodium ions in the blood. Unless the cause is obvious, a variety of tests are subsequently run to determine if sodium was lost from the urine, diarrhea, or from **vomiting**. Tests are also used to determine abnormalities in aldosterone or vasopressin levels. The patient's diet and use of diuretics must be considered.

Treatment

The goals of treatment of acute hyponatremia are to raise the sodium level above 120 mEq/L and to raise the sodium level rapidly by 4–6 mEq/L within the first 1–2 hours of initiation of treatment. Patients with severe hyponatremia should be treated with an infusion of hypertonic (3%) saline to raise the serum sodium level by 4–6 mEq/L. Further correction could be dangerous and is avoided in most patients unless serious neurological symptoms are present.

Patients exhibiting mild symptoms as a result of chronic hyponatremia should be treated cautiously to avoid serious and irreversible damage to the central nervous system that could be precipitated by rapid and overcorrection of hyponatremia. The goals of therapy

in these patients is slow and cautious correction of serum sodium levels and identification of the cause of the hyponatremia.

Prognosis

Hyponatremia is just one manifestation of a variety of disorders. While hyponatremia can easily be corrected, the prognosis for the underlying condition that causes it varies.

Prevention

Patients who take diuretic medications must be checked regularly for the development of hyponatremia.

Hyponatremia is more likely to occur in infants and in the elderly. Individuals in these groups are less able to express thirst and are also less able to independently regulate their fluid intake. Caregivers of infants and the elderly should be educated regarding the importance of adequate and appropriate fluid intake.

REVISED BY MELINDA GRANGER OBERLEITNER, RN, DNS, APRN, CNS

Hypoparathyroidism

Definition

Hypoparathyroidism is the result of a decrease in production of parathyroid hormones by the parathyroid glands located behind the thyroid glands in the neck. The result is a low level of **calcium** in the blood.

Description

Parathyroid glands consist of four pea-shaped glands located on the back and side of the thyroid gland. The gland produces parathyroid hormone which, along with **vitamin D** and calcitonin, are important for the regulation of the calcium level in the body. Hypoparathyroidism affects both males and females of all ages.

Causes and symptoms

The accidental removal of the parathyroid glands during neck surgery is the most frequent cause of hypoparathyroidism. Complications of surgery on the parathyroid glands is another common cause of this disorder. There is the possibility of autoimmune genetic disorders causing hypoparathyroidism such as Hashimoto's **thyroiditis**, **pernicious anemia**, and Addison's disease. The destruction of the gland by radiation is a rare cause of hypoparathyroidism. Occasionally, the parathyroids are absent at birth causing low calcium levels and possible convulsions in the newborn. Symptoms in the advanced and continuous stages of hypoparathyroidism include splitting of the nails, inadequate tooth development and **intellectual disability** (ID) in children, and seizures.

Abnormal low levels of calcium result in irritability of nerves, causing **numbness and tingling** of the hands and feet, with painful-cramp like **muscle spasms** known as tetany. Laryngeal spasms may also occur causing respiratory obstruction.

Diagnosis

Diagnostic measures begin with the individual's own observation of symptoms. A thorough medical history and **physical examination** by a physician is always required for an accurate diagnosis. The general practitioner may refer the individual to an endocrinologist, a medical specialist who studies the function of the parathyroid glands as well as other hormone producing glands. Laboratory studies include blood and urine tests to help determine phosphate and calcium levels. X rays are useful to determine any abnormalities in bone density associated with abnormal calcium levels. These **autoimmune disorders** may accompany hypoparathyroidism, but are not an actual cause of it.

Treatment

In the event of severe muscle spasms, hospitalization may be warranted for calcium injections. Raising carbon-dioxide levels in the blood, which can decrease muscle spasms, may be achieved in immediate situations by placing a paper bag over the mouth and blowing into it to "reuse" each breath. It is critical to obtain timely periodic laboratory tests to check calcium

WWW.BOOKBAZ.IR

levels. A high calcium, low-phosphorous diet may be of significance and is directed by the physician or dietitian.

Prognosis

Presently hypoparathyroidism is considered incurable. The disorder requires lifelong replacement therapy to control symptoms. Medical research continues to search for a cure.

Prevention

There are no specific preventive measures for hypoparathyroidism. However, careful surgical techniques are critical to reduce the risk of damage to the gland during surgery.

Hypophysectomy

Definition

Hypophysectomy or hypophysis is the removal of the pituitary gland.

Purpose

The pituitary gland is in the middle of the head. Removing this master gland is a drastic step that was taken in the extreme circumstance of two cancers that had escaped all other forms of treatment. Cancers of the female breast and male prostate grow faster in the presence of sex hormones. It used to be that sex hormones could be suppressed only by removing their source, the glands that made them. After the gonads were removed, some cancers continued to grow, so other stimulants to their growth had to removed. At this point, some cancer specialists turned to the pituitary.

With the development of new therapeutic agents and methods, especially new ways to manipulate hormones without removing their source, this type of endocrine surgery has been largely relegated to history. However, tumors develop in the pituitary gland that require removal of the tumor but partially preserving the gland.

Description

There are several surgical approaches to the pituitary. The surgeon will choose the best one for the specific procedure. The pituitary lies directly behind the nose, and access through the nose or the sinuses is often the best approach. Opening the skull and lifting the frontal lobe of the brain will expose the delicate neck of the pituitary gland. This approach works best if tumors have extended above the pituitary fossa (the cavity in which the gland lies).

Newer surgical methods using technology have made other approaches possible. Stereotaxis is a three-dimensional aiming technique using x rays or scans for guidance. Instruments can be placed in the brain with pinpoint accuracy through tiny holes in the skull. These instruments can then manipulate brain tissue, either to destroy it or remove it. Stereotaxis is also used to direct radiation with similar precision using a gamma knife. Access to some brain lesions can be gained through the blood vessels using tiny tubes and wires guided by x rays.

Preparation

Pituitary surgery is performed by neurosurgeons deep inside the skull. All the patient can do to prepare is keep as healthy as possible. Informed surgical consent is important so that the patient is fully confident of the need for surgery and the expected outcome.

Aftercare

Routine post-operative care is required. In addition, pituitary function will be assessed.

Risks

The risks of surgery are multiple. Procedures are painstakingly selected to minimize risk and maximize benefit. Unique to surgery on the pituitary is the risk of destroying the entire gland and leaving the entire endocrine system without guidance. This used to be the whole purpose of hypophysectomy. After the procedure, the endocrinologist, a physician specializing in the study and care of the endocrine system, would provide the patient with all the hormones needed. Patients with no pituitary function do quite well because of the available hormone replacements.

Results

Complete removal of the pituitary was the goal for cancer treatment. In the early twenty-first

century, removal of tumors with preservation of the gland is the goal.

Abnormal results

Tumors may not be completely removed, due to their attachment to vital structures.

Hypopituitarism

Definition

Hypopituitarism is loss of function in an endocrine gland due to failure of the pituitary gland to secrete hormones that stimulate that gland's function. The pituitary gland is located at the base of the brain. Patients diagnosed with hypopituitarism may be deficient in one single hormone, several hormones, or have complete pituitary failure.

Description

The pituitary is a pea-sized gland located at the base of the brain, and surrounded by bone. The hypothalamus, another endocrine organ in the brain, controls the function of the pituitary gland by providing "hormonal orders." In turn, the pituitary gland regulates the many hormones that control various functions and organs within the body. The posterior pituitary acts as a sort of storage area for the hypothalamus and passes on hormones that control function of the muscles and kidneys. The anterior pituitary produces its own hormones that help to regulate several endocrine functions.

In hypopituitarism, something interferes with the production and release of these hormones, thus affecting the function of the target gland. Commonly affected hormones may include:

Gonadotropin deficiency

Gonadotropin deficiency involves two distinct hormones affecting the reproductive system. Luteinizing hormone (LH) stimulates the testes in men and the ovaries in women. This deficiency can affect fertility in men and women and menstruation in women. Follicle-stimulating hormone (FSH) has similar effects to LH.

Thyroid stimulating hormone deficiency

Thyroid stimulating hormone (TSH) is involved in stimulation of the thyroid gland. A lack of stimulation in the gland leads to **hypothyroidism**.

Adrenocorticotopic hormone deficiency

Also known as corticotropin, adrenocorticotopic hormone (ACTH) stimulates the adrenal gland to produce a hormone similar to cortisone, called cortisol. The loss of this hormone can lead to serious problems.

Growth hormone deficiency

Growth hormone (GH) regulates the body's growth. Patients who lose supply of this hormone before physical maturity will have impaired growth. Loss of the hormone can also affect adults.

Other hormone deficiencies

Prolactin stimulates the female breast to produce milk. A hormone produced by the posterior pituitary, antidiuretic hormone (ADH), controls the function of the kidneys. When this hormone is deficient, **diabetes insipidus** can result. However, patients with hypopituitarism rarely have ADH deficiency, unless the hypopituitarism is the result of hypothalamus disease.

Multiple hormone deficiencies

Deficiency of a single pituitary hormone occurs less commonly than deficiency of more than one hormone. Sometimes referred to as progressive pituitary hormone deficiency or partial hypopituitarism, there is usually a predictable order of hormone loss. Generally, GH is lost first, then LH deficiency follows. The loss of FSH, TSH and ACTH follow much later. The progressive loss of pituitary hormone secretion is usually a slow process that can occur over a period of months or years. Hypopituitarism does occasionally start suddenly with rapid onset of symptoms.

Panhypopituitarism

This condition represents the loss of all hormones released by the anterior pituitary gland. Panhypopituitarism is also known as complete pituitary failure.

WWW.BOOKBAZ.IR

Causes and symptoms

There are three major mechanisms that lead to the development of hypopituitarism. The first involves decreased release of hypothalamic hormones that stimulate pituitary function. The cause of decreased hypothalamic function may be congenital or acquired through interference such as tumors, inflammation, infection, mass lesions or interruption of blood supply. A second category of causes is any event or mass that interrupts the delivery of hormones from the hypothalamus. These may include particular tumors and aneurysms. Damage to the pituitary stalk from injury or surgery can also lead to hypopituitarism.

The third cause of hypopituitarism is damage to the pituitary gland cells. Destroyed cells can not produce the pituitary hormones that would normally be secreted by the gland. Cells may be destroyed by a number of tumors and diseases. Hypopituitarism is often caused by tumors, the most common of which is pituitary adenoma.

Symptoms of hypopituitarism vary with the affected hormones and severity of deficiency. Frequently, patients have had years of symptoms that were nonspecific until a major illness or **stress** occurred. Overall symptoms may include **fatigue**, sensitivity to cold, weakness, decreased appetite, weight loss and abdominal **pain**. Low blood pressure, **headache** and visual disturbances are other associated symptoms.

Gonadotropin deficiency

Symptoms specific to this hormone deficiency include decreased interest in sex for women and **infertility** in women and men. Women may also have premature cessation of menstruation, hot flashes, vaginal dryness and pain during intercourse. Women who are postmenopausal will not have obvious symptoms such as these and may first present with headache or loss of vision. Men may also have **sexual dysfunction** as a result of gonadotropin deficiency. In acquired gonadotropin deficiency, both men and women may notice loss of body hair.

Thyroid stimulating hormone deficiency

Intolerance to cold; fatigue; weight gain; **constipation**; and pale, waxy and dry skin indicate thyroid hormone deficiency.

Adrenocorticotopic hormone deficiency

Symptoms of ACTH deficiency include fatigue, weakness, weight loss, and low blood pressure. Nausea, pale skin, and loss of pubic and armpit hair in women may also indicate deficiency of ACTH.

Growth hormone deficiency

In children, growth hormone deficiency will result in short stature and growth retardation. Symptoms such as **obesity** and skin wrinkling may or may not show in adults and normal release of growth hormone normally declines with age.

Other hormone deficiencies

Prolactin deficiency is rare and is the result of partial or generalized anterior pituitary failure. When present, the symptom is absence of milk production in women. There are no known symptoms for men. ADH deficiency may produce symptoms of diabetes insipidus, such as excessive thirst and frequent urination.

Multiple hormone deficiencies

Patients with multiple hormone deficiencies will show symptoms of one or more specific hormone deficiencies or some of the generalized symptoms listed in this article.

Panhypopituitarism

The absence of any pituitary function should show symptoms of one or all of the specific hormone deficiencies. In addition to those symptoms, patients may have dry, pale skin that is finely textured. The face may appear finely wrinkled and contain a disinterested expression.

Diagnosis

Once the diagnosis of a single hormone deficiency is made, it is strongly recommended that tests for other hormone deficiencies be conducted.

Gonadotropin deficiency

The detection of low levels of gonadotropin can be accomplished through simple blood tests that measure LH and FSH, simultaneously with gonadal steroid levels. The combination of results can indicate to a physician if the cause of decreased hormone levels or function belongs to hypopituitarism or some sort of primary gonadal failure. Diagnosis will vary among men and women.

Thyroid stimulating hormone deficiency

Laboratory tests measuring thyroid function can help determine a diagnosis of TSH deficiency. The commonly used tests are T4 and TSH measurement done simultaneously to determine the reserve, or pool, of TSH.

Adrenocorticotopic hormone deficiency

An insulin tolerance test may be given to determine if cortisol levels rise when **hypoglycemia** is induced. If they do not rise, there is insufficient reserve of cortisol, indicating an ACTH deficiency. If the insulin tolerance test is not safe for a particular patient, a glucagon test offers similar results. A CRH (corticotropin-releasing hormone) test may also be given. It involves injection of CRH to measure, through regularly drawn blood samples, a resulting rise in ACTH and cortisol. Other tests that stimulate ACTH may be ordered.

Growth hormone deficiency

Growth hormone deficiency is measured through the use of insulin-like growth factor I tests, which measure growth factors that are dependent on growth hormones. Sleep and **exercise** studies may also be used to test for growth hormone deficiency, since these activities are known to stimulate growth hormone secretion. Several drugs also induce secretion of growth hormone and may be given to measure hormone response. The standard test for growth hormone deficiency is the insulin-induced hypoglycemia test. This test does carry some risk from the induced hypoglycemia. Other tests include an arginine infusion test, clonidine test and growth-hormone releasing hormone test.

Other hormone deficiencies

If a test calculates normal levels of prolactin, deficiency of the hormone is eliminated as a diagnosis. A TRH (thyrotropin-releasing hormone) simulation test can determine prolactin levels. A number of tests are available to detect ADH levels and to determine diagnosis of diabetes insipidus.

Multiple and general hypopituitarism tests

Physicians should be aware that nonspecific symptoms can indicate deficiency of one or more hormones and should conduct a thorough clinical history. In general, diagnosis of hypopituitarism can be accomplished with a combination of dynamic tests and simple blood tests, as well as imaging exams. Most of these tests can be conducted in an outpatient lab or **radiology** facility. **Magnetic resonance imaging** (MRI) exams with gadolinium contrast enhancement are preferred imaging exams to study the region of the hypothalamus and pituitary gland. When an MRI is not available, a properly conducted computed tomography scan (CT scan) exam can take its place. These exams can confirm a tumor or other mass, which may be interfering with pituitary function.

Panhypopituitarism

The insulin-induced hypoglycemia, or insulin tolerance test, which is used to determine specific hormone deficiencies, is an excellent test to diagnose panhypopituitarism. This test can reveal levels of growth hormone, ACTH (cortisol) and prolactin deficiency. The presence of insufficient levels of all of these hormones is a good indication of complete pituitary failure. Imaging studies and clinical history are also important.

Treatment

Treatment differs widely, depending on the age and sex of the patient, severity of the deficiency, the number of hormones involved, and even the underlying cause of the hypopituitarism. Immediate hormone replacement is generally administered to replace the specific deficient hormone. Patient education is encouraged to help patients manage the impact of their hormone deficiency on daily life. For instance, certain illnesses, accidents or surgical procedures may have adverse complications due to hypopituitarism.

Gonadotropin deficiency

Replacement of gonadal **steroids** is common treatment for LH and FSH deficiency. Estrogen for women and testosterone for men will be prescribed in the lowest effective dosage possible, since there can be complications to this therapy. To correct women's loss of libido, small doses of androgens may be prescribed. To restore fertility in men, regular hormone injections may be required. Male and female patients whose hypopituitarism results from hypothalamic disease may be successfully treated with a hypothalamic releasing hormone (GnRH), which can restore gonadal function and fertility.

Thyroid stimulating hormone deficiency

In patients who have hypothyroidism, the function of the adrenal glands will be tested and treated with steroids before administering thyroid hormone replacement.

WWW.BOOKBAZ.IR

Adrenocorticotopic hormone deficiency

Hydrocortisone or cortisone in divided doses may be given to replace this hormone deficiency. Most patients require 20 mg or less of hydrocortisone per day.

Growth hormone deficiency

It is essential to treat children with a growth hormone deficiency. The effectiveness of growth hormone therapy in adults, particularly elderly adults, is not as well documented. It is thought to help restore normal muscle to fat ratios. Growth hormone is an expensive and cautiously prescribed treatment.

Treatment of multiple deficiencies and panhypopituitarism

The treatment of hypopituitarism is usually very straightforward, but must normally continue for the remainder of the patient's life. Some patients may receive treatment with GnRH, the hypothalamic hormone. In most cases, treatment will be based on the specific deficiency demonstrated. Patients with hypopituitarism should be followed regularly to measure treatment effectiveness and to avoid overtreatment with hormone therapy. If the cause of the disorder is a tumor or lesion, radiation or surgical removal are treatment options. Successful removal may reverse the hypopituitarism. However, even after removal of the mass, **hormone replacement therapy** may still be necessary.

Prognosis

The prognosis for most patients with hypopituitarism is excellent. As long as therapy is continued, many experience normal life spans. However, hypopituitarism is usually a permanent condition and the prognosis depends on the primary cause of the disorder. It can be potentially life threatening, particularly when acute hypopituitarism occurs as a result of a large pituitary tumor. Morbidity from the disease has increased, although the cause is not known. It is possible that increased morbidity and death are due to overtreatment with hormones. Any time that recovery of pituitary function can occur is preferred to lifelong hormone therapy.

Prevention

There is no known prevention of hypopituitarism, except for prevention of damage to the pituitary/hypothalamic area from injury.

Hypoplastic anemia *see* **Aplastic anemia**

Hypospadias and epispadias

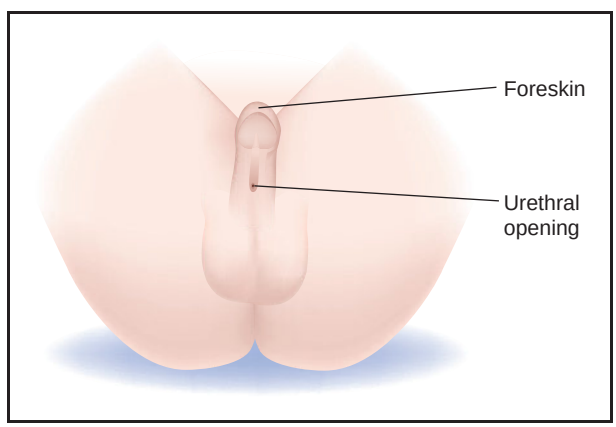
Definition

Hypospadias is a congenital defect, primarily of males, in which the urethra opens on the underside (ventrum) of the penis. It is one of the most common congenital abnormalities in the United States, occurring in about 1 of every 125 live male births. The corresponding defect in females is an opening of the urethra into the vagina and is rare.

Epispadias (also called bladder exstrophy) is a congenital defect of males in which the urethra opens on the upper surface (dorsum) of the penis. The corresponding defect in females is a fissure in the upper wall of the urethra and is quite rare.

Description

In a male, the external opening of the urinary tract (external meatus) is normally located at the tip of the



In hypospadias, the urethra opens along the penile shaft rather than at the penile tip. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

penis. In a female, it is normally located between the clitoris and the vagina.

In males with hypospadias, the urethra opens on the inferior surface or underside of the penis. In females with hypospadias, the urethra opens into the cavity of the vagina.

In males with epispadias, the urethra opens on the superior surface or upper side of the penis. In females with epispadias, there is a crack or fissure in the wall of the urethra and out of the body through an opening in the skin above the clitoris.

During the embryological development of males, a groove of tissue folds inward and then fuses to form a tube that becomes the urethra. Hypospadias occurs when the tube does not form or does not fuse completely. Epispadias is due to a defect in the tissue that folds inward to form the urethra.

During the development of a female, similar processes occur to form the urethra. The problem usually is insufficient length of the tube that becomes the urethra. As a result, the urethra opens in an abnormal location, resulting in a hypospadias. Occasionally, fissures form in the bladder. These may extend to the surface of the abdomen and fuse with the adjacent skin. This condition is most commonly identified as a defect in the bladder although it is technically an epispadias.

Hypospadias in males generally occur alone. Female hypospadias may be associated with abnormalities of the genital tract, since the urinary and genital tracts are formed in the same embryonic process.

Because it represents incomplete development of the penis, some experts think that insufficient male hormone may be responsible for hypospadias.

In males, the incidence of hypospadias is approximately one per 250 to 300 live births. Epispadias is much less common, having an incidence of about one per 100,000 live male births.

In females, hypospadias is much less common than in males. It appears about once in every 500,000 live female births. Epispadias is even more rare. Reliable estimates of the prevalence of epispadias in females are not available. Epispadias in females is often diagnosed and recorded as a bladder anomaly.

Causes and symptoms

Hypospadias and epispadias are congenital defects of the urinary tract. This means they occur during intrauterine development. There is no genetic basis for the defects. Specific causes for hypospadias are not known. This means that blood relatives do not have increased chances of developing them. Reports have shown some rise in prevalence of hypospadias among offspring of mothers who work in certain occupations where they may be exposed to chemicals that disrupt the endocrine system. However, a large trial ending in 2003 showed that aside from a slight increased risk among women who were hairdressers from 1992–1996, there is no evidence that maternal occupation or certain chemical exposure increases risk of hypospadias. The role of chemicals in the development of the defect remains uncertain.

Concern was once raised that use of the antihistamine loratadine (Claritin) early in **pregnancy** might cause hypospadias. However, a national clinical trial revealed in 2004 that there was no link between the drug and risk of second- or third–degree hypospadias.

Hypospadias usually is not associated with other defects of the penis or urethra. In males, it can occur at any site along the underside of the penis. In females, the urethra exits the body in an abnormal location. This usually is due to inadequate length of the urethra.

Epispadias is associated with bladder abnormalities. In females, the front wall of the bladder does not fuse or close. The bladder fissure may extend to the external abdominal wall. In such a rare case, the front of the pelvis also is widely separated. In males, the bladder fissure extends into the urethra and simply becomes an opening somewhere along the upper surface of the penis.

Hypospadias is associated with difficulty in assigning gender to babies. This occurs when gender is not obvious at birth because of deformities in the sex organs.

Diagnosis

Male external urinary tract defects are discovered at birth during the first detailed examination of the newborn. Female urethral defects may not be discovered for some time due to the difficulty in viewing the infant vagina.

Treatment

Surgery is the treatment of choice for both hypospadias and epispadias. All surgical repairs should be undertaken early and completed without delay. This minimizes psychological **trauma**.

In males with hypospadias, one surgery usually is sufficient to repair the defect. With more complicated hypospadias (more than one abnormally situated urethral opening), multiple surgeries may be required. In females with hypospadias, surgical repair technically is more complicated but can usually be completed in a brief interval of time.

WWW.BOOKBAZ.IR

KEY TERMS

Continence—Control of urination or bowel movement.

Urethra—The tube through which urine passes from the bladder to the outside of the body.

Repairing an epispadias is more difficult. In males, this may involve other structures in the penis. Males should not be circumcised since the foreskin often is needed for the repair. Unfortunately, choices may be required that affect the ability to inseminate a female partner. Reproduction requires that the urethral meatus be close to the tip of the penis. Cosmetic appearance and ability to urinate (urinary continence) usually are the primary goals. Surgery for these defects is successful 70–80% of the time. Modern treatment of complete male epispadias allows for an excellent genital appearance and achievement of urinary continence.

In females, repair of epispadias may require multiple surgical procedures. Urinary continence and cosmetic appearance are the usual primary considerations. Urinary continence usually is achieved although cosmetic appearance may be somewhat compromised. Fertility is not usually affected. Repair rates that are similar or better than those for males usually can be achieved for females.

Hypospadias in both males and females is more of a nuisance and hindrance to reproduction than a threat to health. If surgery is not an option, the condition may be allowed to persist. This usually leads to an increased risk of infections in the lower urinary tract.

Prognosis

With adequate surgical repair, most males with simple hypospadias can lead normal lives with a penis that appears and functions in a normal manner. This includes fathering children. Females with simple hypospadias also have normal lives, including conceiving and bearing children.

The prognosis for epispadias depends on the extent of the defect. Most males with relatively minor epispadias lead normal lives, including fathering children. As the extent of the defect increases, surgical reconstruction generally is acceptable. However, many of these men are unable to conceive children. Most epispadias in females can be surgically repaired. The chances of residual disfigurement increase as the extent of the epispadias increases. Fertility in females is not generally affected by epispadias.

Hypotension

Definition

Hypotension is the medical term for low blood pressure.

Description

The pressure of the blood in the arteries rises and falls as the heart and muscles handle demands of daily living, such as **exercise**, sleep, and **stress**. Some healthy people have blood pressure well below the average for their age, even though they have a

completely normal heart and blood vessels. This is often true of athletes who are in superior shape. The term "hypotension" is usually used only when blood pressure has fallen so far that enough blood can no longer reach the brain, causing **dizziness** and **fainting**.

Causes and symptoms

Postural hypotension is the most common type of low blood pressure. In this condition, symptoms appear after a person sits up or stands quickly. In normal people, the cardiovascular system must make a quick adjustment to raise blood pressure slightly to account for the change in position. For those with postural hypotension, the blood pressure adjustment is not adequate or it does not happen. Postural hypotension may occur if someone is taking certain drugs or medicine for high blood pressure. It also happens to diabetics when nerve damage has disrupted the reflexes that control blood pressure.

Many people have a chronic problem with low blood pressure that is not particularly serious. This may include people who require certain medications, who are pregnant, have bad veins, or have arteriosclerosis (hardening of the arteries).

The most serious problem with low blood pressure occurs when there is a sudden drop, which can be life-threatening due to widespread ischemia (insufficient supply of blood to an organ due to blockage in an artery). This type of low blood pressure may be due to a wide variety of causes, including:

- trauma with extensive blood loss
- serious burns
- shock from various causes (e.g. anaphylaxis)
- heart attack
- adrenal failure (Addisonian crisis)
- cancer
- severe fever
- serious infection (septicemia)

Diagnosis

Blood pressure is a measure of the pressure in the arteries created by the heart contracting. During the day, a normal person's blood pressure changes constantly, depending on activity. Low blood pressure can be diagnosed by taking the blood pressure with a sphygmomanometer. This is a device with a soft rubber cuff that is inflated around the upper arm until it is tight enough to stop blood flow. The cuff is then slowly deflated until the health care worker, listening to the artery in the arm with a stethoscope, can hear the blood first as a beat forcing its way along the artery. This is the systolic pressure. The cuff is then deflated more until the beat disappears and the blood flows steadily through the open artery; this gives the diastolic pressure.

Blood pressure is recorded as systolic (higher) and diastolic (lower) pressures. A healthy young adult has a blood pressure of about 110/75, which typically rises with age to about 140/90 by age 60 (a reading now considered mildly elevated).

Treatment

Treatment of low blood pressure depends on the underlying cause, which can usually be resolved. For those people with postural hypotension, a medication adjustment may help prevent the problem. These individuals may find that rising more slowly, or getting out of bed in slow stages, helps the problem. Low blood pressure with no other symptoms does not need to be treated.

Prognosis

Low blood pressure as a result of injury or other underlying condition can usually be successfully treated if the **trauma** is not too extensive or is treated in time. Less serious forms of chronic low blood pressure have a good prognosis and do not require treatment.

Hypothermia

Definition

Hypothermia, a potentially fatal condition, occurs when body temperature falls below 95°F (35°C).

Description

Although hypothermia is an obvious danger for people living in cold climates, many cases have occurred when the air temperature is well above the freezing mark. Elderly people, for instance, have succumbed to hypothermia after prolonged exposure to indoor air temperatures of 50–65°F (10–18.3°C). In

WWW.BOOKBAZ.IR

the United States, hypothermia is primarily an urban phenomenon associated with **alcoholism**, drug **addiction**, mental illness, and cold-water immersion accidents. The victims are often homeless male alcoholics. Officially, 11,817 deaths were attributed to hypothermia in the United States from 1979 to 1994, but experts suspect that many fatal cases go unrecognized. Nearly half the victims were 65 or older, with males dominating every age group. Nonwhites were also overrepresented in the statistics. Among males 65 and older, nonwhites outnumbered whites by more than four to one.

Causes and symptoms

Measured orally, a healthy person's body temperature can fluctuate between 97°F (36.1°C) and 100°F (37.8°C). Survival depends on maintaining temperature stability within this range by balancing the heat produced by metabolism with the heat lost to the environment through (for the most part) the skin and lungs. When environmental or other changes cause heat loss to outpace heat production, the brain triggers physiological and behavioral responses to restore the balance. The involuntary muscular activity of shivering, for example, aids heat production by accelerating metabolism. But if the cold **stress** is too great and the body's defenses are overwhelmed, body temperature begins to fall. Hypothermia is considered to begin once body temperature reaches 95°F (35°C), though even smaller drops in temperature can have an adverse effect.

Hypothermia is divided into two types: primary and secondary. Primary hypothermia occurs when the body's heat-balancing mechanisms are working properly but are subjected to extreme cold, whereas secondary hypothermia affects people whose heat-balancing mechanisms are impaired in some way and cannot respond adequately to moderate or perhaps even mild cold. Primary hypothermia typically involves exposure to cold air or immersion in cold water. The cold air variety usually takes at least several hours to develop, but immersion hypothermia will occur within about an hour of entering the water, since water draws heat away from the body much faster than air does. In secondary hypothermia, the body's heat-balancing mechanisms can fail for any number of reasons, including strokes, diabetes, **malnutrition**, bacterial infection, thyroid disease, spinal cord injuries (which prevent the brain from receiving crucial temperature-related information from other parts of the body), and the use of medications and other substances that affect the brain or spinal cord. Alcohol is one such substance. In smaller amounts it can put people at risk by interfering with their ability to recognize and avoid cold-weather dangers. In larger amounts it shuts down the body's heat-balancing mechanisms.

Secondary hypothermia is often a threat to the elderly, who may be on medications or who have illnesses that affect their ability to conserve heat. Malnutrition and immobility can also put the elderly at risk. Some medical research suggests that shivering and blood vessel narrowing—two of the body's defenses against cold—may not be triggered as quickly in older people. For these and other reasons, the elderly can, over a period of days or even weeks, fall victim to hypothermia in poorly insulated homes or other surroundings that family, friends, and caregivers may not recognize as life threatening. Another risk for the elderly is the fact that hypothermia can easily be misdiagnosed as a **stroke** or some other common illness of old age.

The signs and symptoms of hypothermia follow a typical course, though the body temperatures at which they occur vary from person to person depending on age, health, and other factors. The impact of hypothermia on the nervous system often becomes apparent quite early. Coordination, for instance, may begin to suffer as soon as body temperature reaches 95°F (35°C). The early signs of hypothermia also include cold and pale skin and intense shivering; the latter stops between 90°F (32.2°C) and 86°F (30°C). As body temperature continues to fall, speech becomes slurred, the muscles go rigid, and the victim becomes disoriented and experiences eyesight problems. Other harmful consequences include **dehydration** as well as liver and kidney failure. Heart rate, respiratory rate, and blood pressure rise during the first stages of hypothermia, but fall once the 90°F (32.2°C) mark is passed. Below 86°F (30°C) most victims are comatose, and below 82°F (27.8°C) the heart's rhythm becomes dangerously disordered. However, even at very low body temperatures, people can survive for several hours and be successfully revived, though they may appear to be dead.

Diagnosis

Information on the patient's prior health and activities often helps doctors establish a correct diagnosis and treatment plan. Pulse, blood pressure, temperature, and respiration require immediate monitoring. Because the temperature of the mouth is not an accurate guide to the body's core temperature, readings are taken at other sites, usually the ear, rectum, or esophagus. Other diagnostic tools include **electrocardiography**, which is used to evaluate heart rhythm, and blood and urine

tests, which provide several kinds of key information; a chest x ray is also required. A computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI) may be needed to check for head and other injuries.

Treatment

Emergency medical help should be summoned whenever a person appears hypothermic. The danger signs include intense shivering; stiffness and numbness in the arms and legs; stumbling and clumsiness; sleepiness, confusion, disorientation, **amnesia**, and irrational behavior; and difficulty speaking. Until emergency help arrives, a victim of outdoor hypothermia should be brought to shelter and warmed by removing wet clothing and footwear, drying the skin, and wrapping him or her in warm blankets or a sleeping bag. Gentle handling is necessary when moving the victim to avoid disturbing the heart. Rubbing the skin or giving the victim alcohol can be harmful, though warm drinks such as clear soup and tea are recommended for those who can swallow. Anyone who aids a victim of hypothermia should also look for signs of frostbite and be aware that attempting to rewarm a frostbitten area of the body before emergency help arrives can be extremely dangerous. For this reason, frostbitten areas must be kept away from heat sources such as campfires and car heaters.

Rewarming is the essence of hospital treatment for hypothermia. How rewarming proceeds depends on the body temperature. Different approaches are used for patients who are mildly hypothermic (the patient's body temperature is 90–95°F [32.2–35°C]), moderately hypothermic (86–90°F [30–32.2°C]), or severely hypothermic (less than 86°F [30°C]). Other considerations, such as the patient's age or the condition of the heart, can also influence treatment choices.

Mild hypothermia is reversed with passive rewarming. This technique relies on the patient's own metabolism to rewarm the body. Once wet clothing is removed and the skin is dried, the patient is covered with blankets and placed in a warm room. The goal is to raise the patient's temperature by 0.9–3.6°F (0.5–2°C) an hour.

Moderate hypothermia is often treated first with active external rewarming and then with passive rewarming. Active external rewarming involves applying heat to the skin, for instance by placing the patient in a warm bath or wrapping the patient in electric heating blankets.

Severe hypothermia requires active internal rewarming, which is recommended for some cases of moderate hypothermia as well. There are several types of active internal rewarming. Cardiopulmonary bypass, in which the patient's blood is circulated through a rewarming device and then returned to the body, is considered the best, and can raise body temperature by 1.8–3.6°F (1–2°C) every 3–5 minutes. However, many hospitals are not equipped to offer this treatment. The alternative is to introduce warm oxygen or fluids into the body.

Hypothermia treatment can also include, among other things, insulin, **antibiotics**, and fluid replacement therapy. When the heart has stopped, both **cardiopulmonary resuscitation** (CPR) and rewarming are necessary. Once a patient's condition has stabilized, he or she may need treatment for an underlying problem such as alcoholism or thyroid disease.

Prognosis

Patients with mild or moderate hypothermia usually make a complete recovery. In regard to severely hypothermic patients, the prognosis for survival varies due to differences in people's physiological responses to cold.

Prevention

People who spend time outdoors in cold weather can reduce heat loss by wearing their clothing loosely and in layers and by keeping their hands, feet, and head well covered (30–50% of body heat is lost through the head). Because water draws heat away from the body so easily, staying dry is important, and wet clothing and footwear should be replaced as quickly as possible. Wind- and water-resistant outer garments are also crucial. Alcohol should be avoided because it promotes heat loss by expanding the blood vessels that carry body heat to the skin.

Preventing hypothermia among the elderly requires vigilance on the part of family, friends, and caregivers. An elderly person's home should be properly insulated and heated, with living areas kept at a temperature of 70°F (21.1°C). Warm clothing and bedding are essential, as are adequate food, rest, and **exercise**; warming the bed and bedroom before going to sleep is also recommended. Older people who live alone should be visited regularly—at least once a day during very cold weather—to ensure that their health remains sound and that they are taking good care of themselves. For help and advice, family members and others can turn to government and social service agencies. Meals on Wheels and visiting nurse programs, for instance, may be available, and it may be possible to obtain financial aid for winterizing and heating homes.

Hypothyroidism

Definition

Hypothyroidism is a condition in which a person's thyroid gland is not producing enough hormone. It may be caused by an autoimmune disorder, a genetic defect in a newborn, certain medications, surgical removal of the thyroid gland, **radiation therapy** for cancer, and other reasons.

There are three main types of hypothyroidism. The most common is primary hypothyroidism, in which the thyroid does not produce an adequate amount of T_4. Secondary hypothyroidism develops when the pituitary gland does not release enough of the thyroid-stimulating hormone (TSH) that prompts the thyroid to manufacture T_4. Tertiary hypothyroidism results from a malfunction of the hypothalamus, the part of the brain that controls the endocrine system. Drug-induced hypothyroidism, an adverse reaction to medication, occurs in 2 of every 10,000 people, but rarely causes severe hypothyroidism.

Demographics

According to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), between 3% and 5% of the general population in the United States and Canada has some form of hypothyroidism. Apart from cretinism, which affects one child in every 3,000–4,000, hypothyroidism is largely a disease of adults. The most common form of primary hypothyroidism in North America is Hashimoto's disease, an autoimmune disorder that is diagnosed in about 14 women out of every 1,000 and 1 man in every 2,000.

Caucasians and Hispanics (particularly Mexican Americans) in North America have higher rates of hypothyroidism than African Americans. The reason for this difference was not known as of 2014.

Internationally, the most common cause of hypothyroidism is a lack of iodine in the diet. The prevalence of hypothyroidism caused by iodine deficiency in developing countries is 2–5%, increasing to 15% by age 75.

Description

Hypothyroidism is an endocrine disorder; that is, it is caused by underfunctioning of a gland that is part of the endocrine system—a group of small organs located throughout the body that regulate growth, metabolism, tissue function, and emotional mood. The thyroid gland itself is a butterfly-shaped organ weighing 0.5–1.5 oz. (14–42.5 g) in adults that lies at the base of the throat below the Adam's apple and above the collarbone. It takes its name from a Greek word meaning "shield." The thyroid consists of two lobes about 2 inches in. (5 cm) in length (in adults) connected by a thin strip of tissue called the isthmus.

Hypothyroidism develops when the thyroid gland fails to produce or secrete as much thyroxine (T_4) as the body needs. Because T_4 regulates such essential functions as heart rate, digestion, physical growth, and mental development, an insufficient supply of this hormone can slow life-sustaining processes, damage organs and tissues in every part of the body, and lead to life-threatening complications.

Hypothyroidism is not easy to diagnose because its symptoms are found in a number of other diseases; it often comes on slowly; and it may produce few or no symptoms in younger adults. In general, hypothyroidism is characterized by a slowing down of both physical and mental activities.

Risk factors

Risk factors for hypothyroidism include:

- Sex. Women are at greater risk of hypothyroidism than men. The female/male ratio among adults is between 2:1 and 8:1, depending on the age group being studied.
- Age over 50. In one Massachusetts study, 6% of women over 60 and 2.5% of men over 60 were found to be hypothyroid.
- Race. According to the National Institutes of Health (NIH), the rates of hypothyroidism in the United States are highest among Caucasians (5.1%) and Hispanics (4.1%) and lowest among African Americans (1.7%).
- Obesity.
- Having a small body size at birth and low body mass index during childhood.
- Family history of autoimmune disease.

- Having Turner syndrome, a genetic disorder in which a girl is born with only one X chromosome instead of the normal two. Turner syndrome affects 1 in every 2,500 girls.

Causes and symptoms

Causes

The most common causes of hypothyroidism are:

- Hashimoto's disease. This is an autoimmune disorder in which the patient's immune system attacks the thyroid gland, leading to tissue destruction.
- Treatment for hyperthyroidism. People who have been treated for an oversupply of thyroid hormone (hyperthyroidism) with radioactive iodine (iodine-131) may lose their ability to produce enough thyroid hormone.
- Surgery on the thyroid gland.
- Radiation therapy for the treatment of head or neck cancer.
- Medications. Lithium, given to treat some psychiatric disorders, and certain heart medications may affect the functioning of the thyroid gland. Other drugs known to suppress thyroid function include amiodarone, a heart medication; interferon alpha, given to treat cancer; and stavudine, a drug used to treat HIV infection.
- Pregnancy. As many as 10% of women may become hypothyroid in the first year after childbirth, particularly if they have diabetes.
- Viral infections. These can cause a short-term inflammation of the thyroid gland known as thyroiditis in some people.
- A tumor in the pituitary gland. The pituitary gland produces a hormone called thyroid-stimulating hormone (TSH). Low levels of TSH can lead to secondary hypothyroidism.
- Congenital. About 1 baby in every 3,000–4,000 is born with a defective thyroid gland or no gland at all.
- Too little iodine in the diet. This cause of hypothyroidism is most common in developing countries; it is rare in North America and Europe.

Symptoms

Not every patient with an underactive thyroid has the same symptoms or has them with the same severity. Common symptoms of hypothyroidism, however, include the following:

- Increased sensitivity to cold weather.
- Dry, itchy skin and a pale or yellowish complexion.
- Dry brittle hair that falls out easily and nails that break or split.
- Constipation.
- Goiter (swelling in the front of the neck caused by thyroid enlargement).
- Hoarse voice and puffy facial skin.
- Unexplained weight gain of 10–20 pounds lb. (4.5–9 kg), most of which is fluid.
- Sore and aching muscles, most commonly in the shoulders and hips.
- In women, extra-long menstrual periods or unusually heavy bleeding.
- Weak leg muscles.
- Decreased sweating.
- Arthritis.
- Memory loss or difficulty concentrating.
- Slowed heart rate (less than 60 beats per minute) and lowered blood pressure.
- Depression.

Diagnosis

Adults

Hypothyroidism in adults can be difficult to diagnose because many of its early symptoms are not unique to it. In addition, the symptoms typically come on gradually; the person may simply feel tired or less energetic than usual, or develop dry, itchy skin and brittle hair that falls out easily. Hypothyroidism is sometimes referred to as a "silent" disease precisely because the early symptoms may be so mild that no one realizes anything is wrong. The classic symptoms of hypothyroidism—sensitivity to cold, puffy complexion, decreased sweating, and coarse skin—may occur in only 60% of patients. In addition, the patient's loss of energy and low mood may be misdiagnosed as a psychiatric disorder, most commonly major depression. It may take months to years before the person or their doctor begins to suspect a problem with the thyroid gland.

It's important to see a doctor if any of these symptoms appear unexpectedly. People whose hypothyroidism remains undiagnosed and untreated may eventually develop myxedema. Symptoms of this rare but potentially deadly complication include enlarged tongue, swollen facial features, hoarseness, and physical and mental sluggishness.

Myxedema **coma** can cause unresponsiveness; irregular, shallow breathing; and a drop in blood pressure and body temperature. The onset of this medical emergency can be sudden in people who are

WWW.BOOKBAZ.IR

KEY TERMS

Congenital—Present at birth.

Cretinism—A form of hypothyroidism found in some newborns.

Endocrine system—A system of small organs located throughout the body that regulate metabolism, growth and puberty, tissue function, and mood. The thyroid gland is part of the endocrine system.

Endocrinologist—A doctor who specializes in diagnosing and treating disorders of the endocrine glands and the hormones they secrete.

Goiter—A swelling in the neck caused by an enlarged thyroid gland.

Hashimoto's disease—An autoimmune disorder that is the most common cause of primary hypothyroidism. It was the first disease to be recognized as an autoimmune disorder. It is named for a Japanese doctor, Hakaru Hashimoto, who first described it in 1912.

Hormone—A chemical released by specialized cells that affects cells in other parts of the body. Hormones regulate such body processes as growth, metabolism, the immune system, reproduction, hunger, and mood.

Hyperthyroidism—A disease condition in which the thyroid gland produces too much thyroid hormone.

Hypothyroidism—A disease condition in which the thyroid gland does not produce enough thyroid hormone.

Metabolism—The chemical changes in living cells in which new materials are taken in and energy is provided for vital processes.

Myxedema—A synonym for hypothyroidism. Myxedema coma is a condition in which a person with untreated hypothyroidism loses consciousness. It is potentially fatal.

Thyroid-stimulating hormone (TSH)—A hormone produced by the pituitary gland that stimulates the thyroid gland to produce the hormones that regulate metabolism. Also called thyrotropin.

Thyroiditis—Inflammation of the thyroid gland. It can be caused by a viral infection, a malfunction of the immune system, or certain medications.

Thyroxine (T_4)—The thyroid hormone that regulates many essential body processes.

Triiodothyronine (T_3)—A thyroid hormone similar to thyroxine but more powerful. Preparations of triiodothyronine are used in treating hypothyroidism.

elderly or have been ill, injured, or exposed to very cold temperatures; have recently had surgery; or use sedatives or antidepressants. Without immediate medical attention, myxedema coma can be fatal.

Children

In the United States, newborn infants between 24 and 72 hours old are tested for congenital thyroid deficiency (cretinism) using a test that measures the levels of thyroxine in the infant's blood. If the levels are low, the physician will likely repeat the blood test to confirm the diagnosis. The physician may take an x ray of the infant's legs. In an infant with hypothyroidism, the ends of the bones have an immature appearance. Treatment within the first few months of life can prevent intellectual disabilities (ID) and physical abnormalities.

Older children who develop hypothyroidism may suddenly stop growing. If the child was above average height before the disease occurred, he or she may now be short compared to other children of the same age. Therefore, the most important feature of hypothyroidism in a child is a decrease in the rate of growth in height. If the disease is recognized early and adequately treated, the child will grow at an accelerated rate until reaching the same growth percentile where the child measured before the onset of hypothyroidism. Diagnosis of hypothyroidism in school-age children is based on the patient's observations, medical history, **physical examination**, and **thyroid function tests**.

Examination

The doctor may notice such signs of hypothyroidism during an office examination as dry skin, facial puffiness, a **goiter** in the neck, thin or brittle hair, poor muscle tone, pale complexion, and a slower than normal heart rate. However, it is possible for a person with hypothyroidism not to have these symptoms.

Tests

The diagnosis of hypothyroidism is usually made by tests of the patient's thyroid function following a careful history of the patient's symptoms. The first test is a blood test for TSH. TSH is a hormone produced by the pituitary gland in the brain that stimulates the

thyroid gland to produce thyroid hormone. When the thyroid gland is not producing enough hormone, the pituitary gland secretes more TSH; thus a high level of TSH in the blood indicates that the thyroid gland is not as active as it should be.

The TSH test does not always detect borderline cases of hypothyroidism. The doctor may order additional tests to measure the levels of thyroid hormone as well as TSH in the patient's blood. If the doctor thinks that the patient may have Hashimoto's disease, he or she may test for the presence of abnormal antibodies in the blood. Because Hashimoto's disease is an autoimmune disorder, there will be two or three types of anti-thyroid antibodies in the patient's blood in about 90% of cases

A woman being tested for hypothyroidism should let her doctor know if she is pregnant or **breastfeeding** and all patients should be sure their doctors are aware of any recent procedures involving radioactive materials or contrast media.

Procedures

In some cases, the doctor may order an **ultrasound** study of the patient's neck in order to evaluate the size of the thyroid gland or take a small sample of thyroid tissue in order to make sure that the gland is not cancerous. The usual procedure for obtaining the tissue sample is a fine-needle aspiration biopsy (FNAB). To perform a FNAB, the doctor inserts a thin needle into the thyroid to extract a sample of cells for examination under a microscope. The doctor usually uses an ultrasound monitor to guide the needle. A FNAB can be performed in an outpatient clinic or a doctor's office; it is safer and less invasive than an open surgical biopsy.

Treatment

Traditional

Medications are the treatment of choice for hypothyroidism.

Drugs

Treatment for hypothyroidism consists of a daily dose of a synthetic form of thyroid hormone sold under the trade names of Synthroid, Levothroid, or Levoxyl. The patient is told that the drug must be taken as directed for the rest of his or her life.

In the early weeks of treatment, the patient will need to see the doctor every four to six weeks to have their TSH level checked and the dose of medication adjusted. After the doctor is satisfied with the dosage level and the patient's overall health, checkups are done every six to 12 months. The reason for this careful measurement of the medication is that too much of the synthetic hormone increases the risk of **osteoporosis** in later life or abnormal heart rhythms in the present. **Aging**, other medications, and changes in weight and general health can also affect how much replacement hormone a patient needs, and regular TSH tests are used to monitor hormone levels. Patients should not switch from one brand of thyroid hormone to another without a doctor's permission.

Medications and over-the-counter preparations that can affect the body's absorption of synthetic thyroid hormone include cholestyramine (Questran), **antacids** that contain aluminum hydroxide, **calcium** supplements, and iron supplements. A high intake of soy products or a diet high in fiber can also affect the body's absorption of the hormone, and the patient's doctor may need to adjust the dosage.

Congenital hypothyroidism or cretinism is also treated with synthetic thyroid hormone. Most hospitals now screen newborns for thyroid problems, because untreated cretinism can lead to lifelong physical and mental developmental disorders.

Regular **exercise** and a high-fiber diet can help maintain thyroid function and prevent **constipation**.

Alternatives

Alternative treatments are primarily aimed at strengthening the thyroid and will not eliminate the need for thyroid hormone medications. Herbal remedies to improve thyroid function and relieve symptoms of hypothyroidism include bladder wrack (*Fucus vesiculosus*), which can be taken in capsule form or as a tea. Some foods, including cabbage, peaches, radishes, soybeans, peanuts, and spinach, can interfere with the production of **thyroid hormones**. Anyone with hypothyroidism may want to avoid these foods.

The Shoulder Stand **yoga** position (at least once daily for 20 minutes) is believed to improve thyroid function.

One alternative treatment for hypothyroidism that should not be used is coconut oil. There is no evidence that coconut oil stimulates the thyroid gland, and a few studies suggest that it may actually lower thyroid function.

Prognosis

The prognosis for patients with hypothyroidism is very good, provided they take their medication as directed. They can usually live a normal life with a

WWW.BOOKBAZ.IR

normal life expectancy. Children with cretinism have a good prognosis if the disorder is caught and treated early; some develop **learning disorders**, however, in spite of early treatment.

The chief risks to health are related to lack of treatment for hypothyroidism. If low levels of thyroid hormone are not diagnosed and treated, patients are at increased risk of goiter, an enlarged heart, and severe depression. In addition, women with untreated hypothyroidism have a higher risk of giving birth to babies with **cleft palate** and other **birth defects**.

One rare but potentially life-threatening complication of long-term untreated hypothyroidism is myxedema coma. In this condition, which is usually triggered by **stress** or illness, the person becomes extremely sensitive to cold, may be unusually drowsy, or lose consciousness. Heart rate, blood pressure, and breathing may all be abnormally low. Myxedema coma requires emergency treatment in a hospital with intravenous thyroid hormone and intensive care nursing.

Prevention

There are no proven ways to prevent hypothyroidism because the disorder has so many possible causes.

Judith Sims, M.S.
Rebecca J. Frey, PhD

Hypotonic duodenography

Definition

Hypotonic duodenography is an x ray procedure that produces images of the duodenum. The duodenum is the first part of the small intestine.

Purpose

Hypotonic duodenography may be ordered to detect tumors of the head of the pancreas or the area where the pancreatic and bile ducts meet the small intestine. Lesions causing upper abdominal **pain** may be demonstrated by duodenography, and the procedure can aid in the diagnosis of chronic **pancreatitis**.

Precautions

Some patients with narrowing of the tubes in the upper gastrointestinal tract should not receive duodenography. Patients with certain heart disorders and **glaucoma** are cautioned against receiving an agent called anticholinergic, which is administered during the procedure to lessen intestinal **muscle spasms**. A hormone called glucagon may also be used to relax the intestines, but its use is not recommended in patients with most forms of diabetes.

Description

Hypotonic duodenography is also referred to as x ray of the duodenum or simply as duodenography. The patient is seated while the radiologist places a catheter in the nose and down into the stomach. Then the patient lies down and the tube is continued to the duodenum. The radiologist is guided in this placement by a fluoroscopic image. (Fluoroscopic equipment shows an immediate x ray. In this case, the x ray shows the location of the catheter as it is moved into the stomach and duodenum.) Next, either the glucagon is administered intravenously or anticholinergic is injected into the patient to relax the muscles of the intestine.

After several minutes, the physician will administer barium through the catheter. Barium is a contrast agent that will help highlight the area on the fluoroscopy screen and x rays. After a few films are taken, some of the barium is withdrawn and air is sent in through the catheter. Additional images are acquired and the catheter is then removed. The procedure takes 30–60 minutes.

Preparation

Patients are required to fast from midnight before the test until after the test, or about 6–12 hours. Just prior to the exam, patients should remove dentures, glasses, and other objects that may interfere with the procedure. The patient may be instructed to empty his or her bladder just prior to duodenography.

Aftercare

The barium should be expelled within two to three days. Extra fluids and/or an agent given by the physician to help encourage bowel movement may aid in barium elimination. Physicians and patients should watch for possible reactions to the anticholinergic or glucagon. If an anticholinergic is used, patients are advised to empty their bladder within a few hours after the exam and to wait two hours for clearing of vision or have someone drive them home. Patients will notice that their stools are chalky white from the barium for one to three days following the procedure.

Risks

Abdominal cramping may occur when the physician instills air into the duodenum, but aside from the discomfort, there are few risks associated with this procedure. Side effects from the contrast, hormones or agents may occur. Those patients with diabetes, **heart disease**, or glaucoma run the highest risk of reaction and should not receive anticholinergic or glucagon, depending on their specific conditions. Elderly patients or those who are extremely ill, must be closely monitored during the procedure for possible return of fluid, or gastric reflux.

Results

The linings of the duodenum and surrounding tissues will look smooth and even. The shape of the head of the pancreas will appear normal and near the duodenal wall.

Abnormal results

Any masses or irregular nodules on the wall of the duodenum may indicate tumors or abnormality of tissue. Tumors of the head of the pancreas or of the opening into the intestine from the pancreatic and bile ducts may be seen. Chronic pancreatitis may be indicated on the x rays. In many instances, follow-up

WWW.BOOKBAZ.IR

laboratory or imaging studies may be ordered to further study the abnormal findings and confirm a diagnosis.

Hypovolemic shock *see* **Shock**

Hysterectomy

Definition

Hysterectomy is the surgical removal of all or part of the uterus. In a total hysterectomy, the uterus and cervix are removed. In some cases, the fallopian tubes and ovaries are removed along with the uterus, which is a hysterectomy with bilateral **salpingo-oophorectomy**. In a subtotal hysterectomy, only the uterus is removed; the cervix is left in place. In a radical hysterectomy, the uterus, cervix, ovaries, oviducts, lymph nodes, and lymph channels are removed. The type of hysterectomy performed depends on the reason for the procedure. In all cases, menstruation permanently stops and a woman loses the ability to bear children.

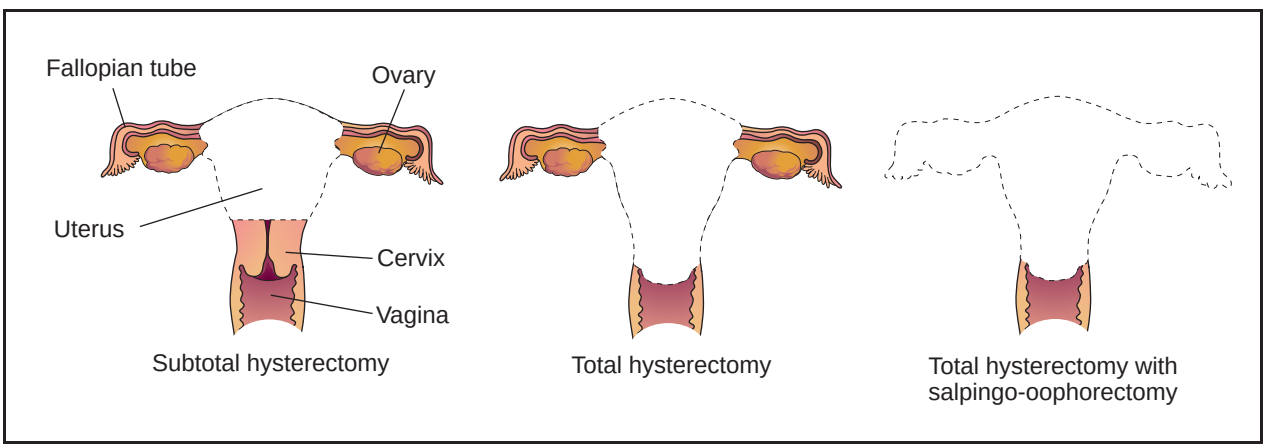
Purpose

The most frequent reason for hysterectomy in American women is to remove fibroid tumors, accounting for 30% of these surgeries. Fibroid tumors are non-cancerous (benign) growths in the uterus that can cause pelvic or **low back pain** and heavy or lengthy menstrual periods. They occur in 30–40% of women over age 40, and are three times more likely to be present in African American women than in Caucasian women. Fibroids do not need to be removed unless they are causing symptoms that interfere with a woman's normal activities.

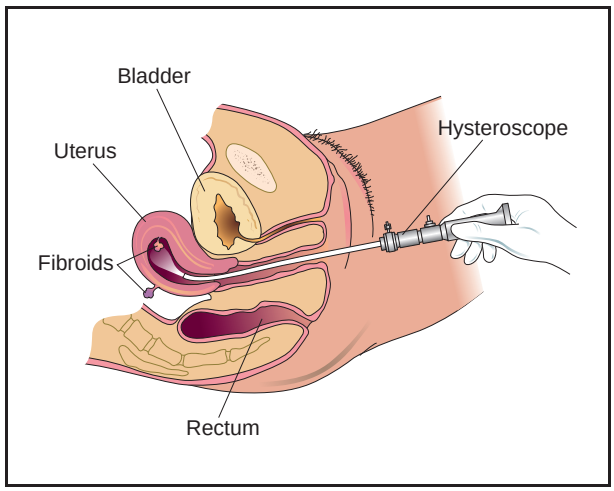
Treatment of **endometriosis** is the reason for 20% of hysterectomies. The endometrium is the lining of the uterus. Endometriosis occurs when the cells from the endometrium begin growing outside the uterus. The outlying endometrial cells respond to the hormones that control the menstrual cycle, bleeding each month the way the lining of the uterus does. This causes irritation of the surrounding tissue, leading to **pain** and scarring.

Twenty percent of hysterectomies are done because of heavy or abnormal vaginal bleeding that cannot be linked to any specific cause and cannot be controlled by other means. Another 20% are performed to treat prolapsed uterus, **pelvic inflammatory disease**, or endometrial hyperplasia, a potentially precancerous condition.

About 10% of hysterectomies are performed to treat cancer of the cervix, ovaries, or uterus. Women with cancer in one or more of these organs almost always have the organ(s) removed as part of their cancer treatment.



Three types of hysterectomies: subtotal, total, and total with salpingo-oophorectomy. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*



Hysteroscopy is a procedure that allows inspection of the uterus by using a telescope-like instrument called a hysteroscope. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

Hysterectomy is the second most common operation performed on women in the United States. About 600,000 of these surgeries are done annually. By age 60, approximately one out of every three American women will have had a hysterectomy. It is estimated that 30% of hysterectomies are unnecessary.

The frequency with which hysterectomies are performed in the United States has been questioned in recent years. It has been suggested that a large number of hysterectomies are performed unnecessarily. The United States has the highest rate of hysterectomies of any country in the world. Also, the frequency of this surgery varies across different regions of the United States. Rates are highest in the South and Midwest, and are higher for African American women. In recent years, although the number of hysterectomies performed has declined, the number of hysterectomies performed on younger women aged 30s and 40s is increasing, and 55% of all hysterectomies are performed on women aged 35–49.

Description

Hysterectomies are usually performed under the strict conditions of a hospital operating room. The procedure is generally performed by a gynecologist, a medical doctor who has specialized in the areas of women's general health, **pregnancy**, labor and **childbirth**, prenatal testing, and genetics.

A hysterectomy is classified according to the structures that are removed during the procedure and the method used to remove them.

Total hysterectomy

A total hysterectomy, sometimes called a simple hysterectomy, removes the entire uterus and the cervix. The ovaries are not removed and continue to secrete hormones. Total hysterectomies are usually performed in the case of uterine and **cervical cancer**. This is the most common kind of hysterectomy.

In addition to a total hysterectomy, a procedure called a bilateral salpingo-oophorectomy is sometimes performed. This surgery removes the ovaries and the fallopian tubes. Removal of the ovaries eliminates the main source of the hormone estrogen, so **menopause** occurs immediately. Removal of the ovaries and fallopian tubes is performed in about one-third of hysterectomy operations, often to reduce the risk of **ovarian cancer**.

Subtotal hysterectomy

If the reason for the hysterectomy is to remove **uterine fibroids**, treat abnormal bleeding, or relieve pelvic pain, it may be possible to remove only the uterus and leave the cervix. This procedure is called a subtotal hysterectomy (or partial hysterectomy), and removes the least amount of tissue. The opening to the cervix is left in place. Some women believe that leaving the cervix intact aids in their achieving sexual satisfaction. This procedure, which used to be rare, is now performed more frequently.

Subtotal hysterectomy is easier to perform than a total hysterectomy, but leaves a woman at risk for cervical cancer. She will still need to have yearly Pap smears.

Radical hysterectomy

Radical hysterectomies are performed on women with cervical cancer or **endometrial cancer** that has spread to the cervix. A radical hysterectomy removes the uterus, cervix, upper part of the vagina, ovaries, fallopian tubes, lymph nodes, lymph channels, and tissue in the pelvic cavity that surrounds the cervix. This type of hysterectomy removes the most tissue and requires the longest hospital stay and a longer recovery period.

Methods of hysterectomy

There are two ways that hysterectomies can be performed. The choice of method depends on the type of hysterectomy, the doctor's experience, and the reason for the hysterectomy.

ABDOMINAL HYSTERECTOMY. About 75% of hysterectomies performed in the United States are abdominal hysterectomies. The surgeon makes a 4–6 in. (10–15 cm) incision either horizontally across the

WWW.BOOKBAZ.IR

KEY TERMS

Cervix—The lower part of the uterus extending into the vagina.

Fallopian tubes—Slender tubes that carry eggs (ova) from the ovaries to the uterus.

Lymph nodes—Small, compact structures lying along the channels that carry lymph, a yellowish fluid. Lymph nodes produce white blood cells (lymphocytes), which are important in forming antibodies that fight disease.

Pap smear—The common term for the Papanicolaou test, a simple smear method of examining stained cells to detect cancer of the cervix.

Prolapsed uterus—A uterus that has slipped out of place, sometimes protruding down through the vagina.

pubic hair line from hip bone to hip bone or vertically from navel to pubic bone. Horizontal incisions leave a less noticeable scar, but vertical incisions give the surgeon a better view of the abdominal cavity. The blood vessels, fallopian tubes, and ligaments are cut away from the uterus, which is lifted out.

Open abdominal hysterectomies take 1–3 hours. The hospital stay is 3–5 days, and it takes 4–8 weeks to return to normal activities.

The advantages of an open abdominal hysterectomy are that the uterus can be removed even when a woman has internal scarring (**adhesions**) from previous surgery or her fibroids are large. The surgeon has a good view of the abdominal cavity and more room to work. Also, surgeons tend to have the most experience with this type of hysterectomy. The abdominal incision is more painful than with vaginal hysterectomy, and the recovery period is longer.

A less invasive abdominal approach is called conventional laparoscopic hysterectomy. Multiple tiny incisions are made in the abdomen, including one through the navel through which a scope is placed. The scope is used to peer into the abdomen and to direct miniature surgical instruments that are inserted through the other small incisions. Robotic-assisted laparoscopic hysterectomy may allow even smaller incisions than the more traditional laparoscopic hysterectomy. The surgeon does not manipulate the tools, rather directing a robotic tool to do so thorough a complex and sophisticated computer interface. This method improves the precision of the procedure, allowing smaller and more precise cuts to be made, and decreasing recovery time. The uterus is cut into small bits that may be removed either through one of the tiny abdominal incisions, or through an incision in the vagina.

VAGINAL HYSTERECTOMY. With a conventional vaginal hysterectomy, the surgeon makes an incision near the top of the vagina. The surgeon then reaches through this incision to cut and tie off the ligaments, blood vessels, and fallopian tubes. Once the uterus is cut free, it is removed through the vagina. The operation takes 1–2 hours. The hospital stay is usually 1–3 days, and the return to normal activities takes about four weeks.

The advantages of this procedure are that it leaves no visible scar and is less painful. The disadvantage is that it is more difficult for the surgeon to see the uterus and surrounding tissue. This makes complications more common. Large fibroids cannot be removed using this technique. It is very difficult to remove the ovaries during a vaginal hysterectomy, so this approach may not be possible when the ovaries are involved.

Laparoscopic-assisted vaginal hysterectomy can also be performed. With this surgery, a tube containing a tiny camera is inserted through an incision in the navel. This allows the surgeon to see the uterus on a video monitor. The surgeon then inserts two slender instruments through small incisions in the abdomen and uses them to cut and tie off the blood vessels, fallopian tubes, and ligaments. When the uterus is detached, it is removed though a small incision at the top of the vagina.

This technique, called laparoscopic-assisted vaginal hysterectomy, allows surgeons to perform a vaginal hysterectomy that might otherwise be too difficult. The hospital stay is usually only one day. Recovery time is about two weeks. The disadvantage is that this operation is relatively new and requires great skill by the surgeon.

Any vaginal hysterectomy may have to be converted to an abdominal hysterectomy during surgery if complications develop.

Precautions

As in all major surgery, the health of the patient affects the risk of the operation. Women who have chronic heart or lung diseases, diabetes, or iron-deficiency anemia may not be good candidates for this operation. Heavy **smoking**, **obesity**, use of steroid drugs, and use of illicit drugs add to the surgical risk.

Preparation

Before surgery the doctor will order blood and urine tests. The woman may also meet with the anesthesiologist to evaluate any special conditions that might affect the administration of **anesthesia**. On the evening before the operation, the woman should eat a light dinner and then have nothing to eat or drink after midnight.

Aftercare

After surgery, a woman will feel some degree of discomfort; this is generally greatest in abdominal hysterectomies because of the incision. In some cases, hysterectomy is performed on an outpatient basis, and the woman goes home the same day. In other cases, hospital stays vary from about one day (laparoscopic- or robotic -assisted vaginal hysterectomy) to one to two days (abdominal hysterectomy with bilateral salpingo-oophorectomy). During the hospital stay, the doctor will probably order more blood tests.

Return to normal activities such as driving and working takes anywhere from 2–8 weeks, again depending on the type of surgery. Some women have emotional changes following a hysterectomy. Women who have had their ovaries removed will probably start **hormone replacement therapy**.

Risks

Hysterectomy is a relatively safe operation, although like all major surgery it carries risks. These include unanticipated reaction to anesthesia, internal bleeding, **blood clots**, damage to other organs such as the bladder, and post-surgery infection.

Other complications sometimes reported after a hysterectomy include:

- urinary problems, including incontinence, frequency and urgency, fistula, and infection
- sexual problems due to decreased sensation, inadequate lubrication, or changes in sex drive
- weight gain
- constipation
- pelvic pain
- decreased ovarian hormone production

Hot flashes and other symptoms of menopause can occur when the ovaries are removed. Women who have both ovaries removed and who do not take estrogen replacement therapy run an increased risk of **heart disease** and **osteoporosis**, a condition that causes bones to become brittle. Women may also experience depressive emotional responses to the surgery; this risk is increased in women with a history of psychological and emotional problems before the hysterectomy.

Results

Although there is some concern that hysterectomies may be performed unnecessarily, there are many conditions for which the operation improves a woman's quality of life. In the Maine Woman's Health Study, 71% of women who had hysterectomies to correct moderate or severe painful symptoms reported feeling better mentally, physically, and sexually after the operation.

Morbidity and mortality rates

The rate of complications differs depending on the type of hysterectomy performed. Abdominal hysterectomy is associated with a higher rate of complications (9.3%), while the overall complication rate for vaginal hysterectomy is 5.3%, and 3.6% for laparoscopic vaginal hysterectomy. The risk of death from hysterectomy is about one in every 1,000 women. The rates of some of the more commonly reported complications are:

- excessive bleeding (hemorrhage): 1.8–3.4%
- fever or infection: 0.8–4.0%
- accidental injury to another organ or structure: 1.5–1.8%

Alternatives

Women for whom a hysterectomy is recommended should discuss possible alternatives with their doctor and consider getting a second opinion, since this is major surgery with life-changing implications. Whether an alternative is appropriate for any individual woman is a decision she and her doctor should make together. Some alternative procedures to hysterectomy include hormonal medications to help shrink fibroids or the uterine lining. Other interventions may include:

- Embolization. During uterine artery embolization, interventional radiologists put a catheter into the artery that leads to the uterus and inject polyvinyl alcohol particles right where the artery leads to the blood vessels that nourish the fibroids. By killing those blood vessels, the fibroids have no more blood supply, and they die. Severe cramping and pain after the procedure is common, but serious complications are less than 5% and the procedure may protect fertility.

WWW.BOOKBAZ.IR

- Myomectomy. A myomectomy is a surgery used to remove fibroids, thus avoiding a hysterectomy. Hysteroscopic myomectomy, in which a surgical hysteroscope (a type of endoscope) is inserted into the uterus through the vagina, can be done on an outpatient basis. If there are large fibroids, an abdominal incision is required. Patients typically are hospitalized for two to three days after the procedure and require up to six weeks recovery. Laparoscopic myomectomies are also being done more often. They only require three small incisions in the abdomen, and have much shorter hospitalization and recovery times. Once the fibroids have been removed, the surgeon must repair the wall of the uterus to eliminate future bleeding or infection.
- Endometrial ablation. In this surgical procedure, recommended for women with small fibroids, the entire lining of the uterus is removed. After undergoing endometrial ablation, patients are no longer fertile. The uterine cavity is filled with fluid and a hysteroscope is inserted to provide a clear view of the uterus. Then, the lining of the uterus is destroyed using a laser beam or electric voltage. The procedure is typically done under anesthesia, although women can go home the same day as the surgery. Another newer procedure involves using a balloon, which is filled with superheated liquid and inflated until it fills the uterus. The liquid kills the lining, and after eight minutes the balloon is removed.
- Endometrial resection. The uterine lining is destroyed during this procedure using an electrosurgical wire loop (similar to endometrial ablation).

Hysteria

Definition

The term "hysteria" has been in use for more than 2,000 years, and its definition has become broader and more diffuse over time. In modern psychology and psychiatry, hysteria is a feature of hysterical disorders in which a patient experiences physical symptoms that have a psychological, rather than an organic, cause. It is defined as an histrionic personality disorder characterized by excessive emotions, dramatics, and attention–seeking behavior.

Description

Hysterical disorders

Patients with hysterical disorders, such as conversion and somatization disorder experience physical symptoms that have no organic cause. Conversion disorder affects motor and sensory functions, while somatization affects the gastrointestinal, nervous, cardiopulmonary, or reproductive systems. These patients are not faking their ailments, as the symptoms are very real to them. Disorders with hysteric features typically begin in adolescence or early adulthood.

Histrionic personality disorder

Histrionic personality disorder has a prevalence of approximately 2-3% in the general population. It

JEAN MARTIN CHARCOT (1825–1893)

(The Library of Congress.)

Jean Martin Charcot was born to a carriage maker on November 29, 1825, in Paris, France. Charcot attended the University of Paris, earning his medical degree in 1853. In 1860, he accepted a position at the university as a professor of pathological anatomy until 1862, when he was named senior physician at the Salpêtrière, a hospital for the treatment of mental illness.

Charcot's research and work on psychoneuroses and hysterical disorders untimately helped to dispell the belief that hysteria was a disorder found only in women. Charcot also explored the possibility that physiological abnormalities of the nervous system played a part when behavioral problems were exhibited. He became known for his ability to diagnose and locate these abnormalities of the central nervous system. Finally, Charcot's most notable contribution to the field of psychiatry was his successful use of hypnotism in the diagnosis and treatment of hysteria. He found that, while hypnotized, the patient recalled details, which were not readily available to the individual in a conscious state. In addition, Charcot found that the therapist could more easily influence the hypnotized patient during therapy. In 1882, Charcot presented his research findings to the French Academy of Sciences with favorable results.

Charcot was a prolific writer and a talented artist. Between 1888 and 1894, his complete works were compiled into nine volumes. His most noted work *Lectures on the Diseases of the Nervous System* was published in 1877. Charcot died on August 16, 1893.

begins in early adulthood and has been diagnosed more frequently in women than in men. Histrionic personalities are typically self–centered and attention seeking. They operate on emotion, rather than fact or logic, and their conversation is full of generalizations and dramatic appeals. While the patient's enthusiasm, flirtatious behavior, and trusting nature may make them appear charming, their need for immediate gratification, mercurial displays of emotion, and constant demand for attention often alienates them from others.

Causes and symptoms

Hysterical disorders

Hysteria may be a defense mechanism to avoid painful emotions by unconsciously transferring this distress to the body. There may be a symbolic function for this behavior. For example a rape victim may develop paralyzed legs. Symptoms may mimic a number of physical and neurological disorders that must be ruled out before a diagnosis of hysteria is made.

Histrionic personality disorder

According to the *Diagnostic and Statistical Manual of Mental Disorders,* Fourth Edition (*DSM–IV*), individuals with histrionic personality possess at least five of the following symptoms or personality features:

- a need to be the center of attention
- inappropriate, sexually seductive, or provocative behavior while interacting with others
- rapidly changing emotions and superficial expression of emotions
- vague and impressionistic speech (gives opinions without any supporting details)
- easily influenced by others
- believes relationships are more intimate than they are

Diagnosis

Hysterical disorders frequently prove to be actual medical or neurological disorders, which makes it important to rule these disorders out before diagnosing a patient with hysterical disorders. In addition to a patient interview, several clinical inventories may be

WWW.BOOKBAZ.IR

KEY TERMS

Psychiatrist—A medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

Psychologist—A mental health professional who treats mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

Psychotherapy—The treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

used to assess the patient for hysterical tendencies, such as the Minnesota Multiphasic Personality Inventory–2 (MMPI–2) or the Millon Clinical Multiaxial Inventory–III (MCMI–III). These tests may be administered in an outpatient or hospital setting by a psychiatrist or psychologist.

Treatment

Hysterical disorders

For people with hysterical disorders, a supportive healthcare environment is critical. Regular appointments with a physician who acknowledges the patient's physical discomfort are important. **Psychotherapy** may be attempted to help the patient gain insight into the cause of their distress. Use of behavioral therapy can help to avoid reinforcing symptoms.

Histrionic personality disorder

Psychotherapy is generally the treatment of choice for histrionic personality disorder. It focuses on supporting the patient and on helping develop the skills needed to create meaningful relationships with others.

Prognosis

Hysterical disorders

The outcome for hysterical disorders varies by type. Somatization is typically a lifelong disorder, while conversion disorder may last for months or years. Symptoms of hysterical disorders may suddenly disappear, only to reappear in another form later.

Histrionic personality disorder

Individuals with histrionic personality disorder may be at a higher risk for suicidal gestures, attempts, or threats in an effort to gain attention. Providing a supportive environment for patients with both hysterical disorders and histrionic personality disorder is key to helping these patients.

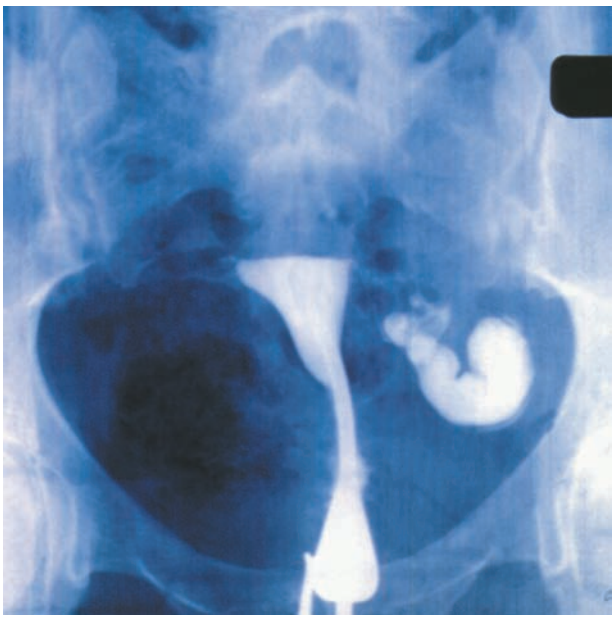
Hysterosalpingography

Definition

Hysterosalpingography is a procedure where x rays are taken of a woman's reproductive tract after a dye is injected. *Hystero* means uterus and *salpingo* means tubes, so hysterosalpingography literally means to take pictures of the uterus and fallopian tubes. This procedure may also be called hysterography (HSG).



A hysterosalpingogram of the abdomen of a woman whose fallopian tubes are blocked. The fallopian tube (right on image) is blocked near the uterus, the triangular shape at center. The other fallopian tube is obstructed at a point further from the uterus where dilatation has occurred. *(Photo Researchers, Inc.)*

Purpose

Hysterosalpingography is used to determine if the fallopian tubes are open, or if there are any apparent abnormalities or defects in the uterus. It can be used to detect tumors, scar tissue, or tears in the lining of the uterus. This procedure is often used to help diagnose **infertility** in women. The fallopian tubes are the location where an egg from the ovary joins with sperm to produce a fertilized ovum. If the fallopian tubes are blocked or deformed, the egg may not be able to descend or the sperm may be blocked from moving up to meet the egg. Up to 30% of all cases of infertility are due to damaged or blocked fallopian tubes.

Precautions

This procedure should not be done on women who suspect they might be pregnant or who may have a pelvic infection. Women who have had an allergic reaction to dye used in previous x-ray procedures should inform their doctor.

Description

As with other types of pelvic examinations, the woman will lie on her back on an examination table with her legs sometimes raised in stirrups. The x-ray equipment is placed above the abdomen.

A speculum is inserted into the vagina and a catheter (a thin tube) is inserted into the uterus through the cervix (the opening to the uterus). A small balloon in the catheter is inflated to hold it in place. A liquid water-based or oil-based dye is then injected through the catheter into the uterus. This process can cause cramping, **pain**, and uterine spasms.

As the dye spreads through the reproductive tract, the doctor may watch for blockages or abnormalities on an x-ray monitor. Several x rays will also be taken. The procedure takes approximately 15–30 minutes. The x rays will be developed while the patient waits, but the final reading and interpretation of the x rays by a radiologist (a doctor who specializes in x rays) may not be available for a few days.

Interestingly, sometimes the hysterosalpingography procedure itself can be considered a treatment. The dye used can sometimes open up small blockages in the fallopian tubes. The need for additional test procedures or surgical treatments to deal with infertility should be discussed with the doctor.

Preparation

This procedure is generally done in the x-ray department of a hospital or large clinic. General **anesthesia** is not needed. A pain reliever may be taken prior to the procedure to lessen the severity of cramping.

Aftercare

While no special aftercare is required after a hysterosalpingography, the woman may be observed for some period after the procedure to ensure that she does not have any allergic reactions to the dye. A sanitary napkin may be worn after the procedure to absorb dye that will flow out through the vaginal opening. If a blockage is seen in a tube, the patient may be given an antibiotic. A woman should notify her doctor if she experiences excessive bleeding, extensive pelvic pain, **fever**, or an unpleasant vaginal odor after the procedure. These symptoms may indicate a pelvic infection. Counseling may be necessary to interpret the results of the x rays, and to discuss any additional procedures to treat tubal blockages or uterine abnormalities found.

Risks

Cramps during the procedure are common. Complications associated with hysterosalpingography include abdominal pain, pelvic infection, and allergic

WWW.BOOKBAZ.IR

reactions. It is also possible that abnormalities of the fallopian tubes and uterus will not be detected by this procedure.

Results

A normal hysterosalpingography will show a healthy, normally shaped uterus and unblocked fallopian tubes.

Abnormal results

Blockage of one or both of the fallopian tubes or abnormalities of the uterus may be detected.

Altha Roberts Edgren

Hysteroscopy

Definition

Hysteroscopy is a procedure that allows a physician to look through the vagina and neck of the uterus (cervix) to inspect the cavity of the uterus. A telescope-like instrument called a hysteroscope is used. Hysteroscopy is used as both a diagnostic and a treatment tool.

Purpose

Diagnostic hysteroscopy may be used to evaluate the cause of **infertility**, to determine the cause of repeated miscarriages, or to help locate polyps and fibroids.

The procedure is also used to treat gynecological conditions, often instead of or in addition to **dilatation and curettage** (D&C). A D&C is a procedure for scraping the lining of the uterus. A D&C can be used to take a sample of the lining of the uterus for analysis. Hysteroscopy is an advance over D&C because the doctor can take tissue samples of specific areas or actually see fibroids, polyps, or structural abnormalities.

When used for treatment, the hysteroscope is used with other devices to remove polyps, fibroids, or IUDs that have become embedded in the wall of the uterus.

Precautions

The procedure is not performed on women with **cervical cancer**, **endometrial cancer**, or acute pelvic inflammation.

Description

Diagnostic hysteroscopy is performed in either a doctor's office or hospital. Before inserting the hysteroscope, the doctor injects a local anesthetic around the cervix. Once it has taken effect, the doctor dilates the cervix and then inserts a narrow lighted tube (the hysteroscope) through the cervix to reveal the inside of the uterus. Ordinarily, the walls of the uterus are touching each other. In order to get a better view, the uterus is inflated with carbon dioxide gas or fluid. Hysteroscopy takes about 30 minutes, and can cost anywhere from $750–$4,000 depending on the extent of the procedure.

Treatment involving the use of hysteroscopy is usually performed as a day surgical procedure with regional or general **anesthesia**. Tiny surgical instruments are inserted through the hysteroscope, and are used to remove polyps or fibroids. A small sample of tissue lining the uterus is often removed for examination, especially if there is any abnormal bleeding.

Preparation

If the procedure is done in the doctor's office, the patient will be given a mild **pain** reliever before the procedure to ease cramping. The doctor will wash the vagina and cervix with an antiseptic solution.

If the procedure is done in the hospital under general anesthesia, the patient should not eat or drink anything (even water) after midnight the night before the procedure.

Aftercare

Many women experience light bleeding for several days after surgical hysteroscopy. Mild cramping or pain is common after operative hysteroscopy, but usually fades away within eight hours. If carbon dioxide gas was used, there may also be some shoulder pain. Nonprescription pain relievers may help ease discomfort. Women may want to take the day off and relax after having hysteroscopy.

Risks

Diagnostic hysteroscopy is a fairly safe procedure that only rarely causes complications. The primary

risk is prolonged bleeding or infection, usually following surgical hysteroscopy to remove a growth.

Very rare complications include perforation of the uterus, bowel, or bladder. Surgery under general anesthesia causes the additional risks typically associated with anesthesia.

Patients should alert their health care provider if they develop any of these symptoms:

- abnormal discharge
- heavy bleeding
- fever over 101°F (38.3°C)
- severe lower abdominal pain

Results

A uterus with no fibroids or other growths would be considered normal and healthy.

Abnormal results

Using hysteroscopy, the doctor may find **uterine fibroids** or polyps (often the cause of abnormal bleeding) or a septum (extra fold of tissue down the center of the uterus) that can cause infertility. Sometimes, precancerous or malignant growths are discovered.

PERIODICALS

Anon. "Looking Inside the Uterus." *Harvard Women's Health Watch* 4, no. 5 (January 1997): 4-5.

Carol A. Turkington

Hysterosonography

Definition

Hysterosonography, which is also called sonohysterography, is a new noninvasive technique that involves the slow infusion of sterile saline solution into a woman's uterus during **ultrasound** imaging. Hysterosonography allows the doctor to evaluate abnormal growths inside the uterus; abnormalities of the tissue lining the uterus (the endometrium); or disorders affecting deeper tissue layers. Hysterosonography does not require either radiation or contrast media, or invasive surgical procedures

Purpose

Hysterosonography is used to evaluate patients in the following groups:

- peri- or postmenopausal women with unexplained vaginal bleeding
- women whose endometrium appears abnormal during baseline ultrasound imaging
- women with fertility problems. Infertility is sometimes related to polyps, leiomyomas (fibroids), or adhesions inside the uterus. Adhesions are areas of tissue that have grown together to form bands or membranes across the inside of the uterus.
- women receiving tamoxifen therapy for breast cancer

Hysterosonography is useful as a screening test to minimize the use of more invasive diagnostic procedures, such as tissue biopsies and **dilatation and curettage** (D&C). Hysterosonography can also be used as a follow-up after uterine surgery to evaluate its success.

Precautions

Hysterosonography is difficult to perform in patients with certain abnormalities, including:

- Cervical stenosis. Cervical stenosis means that the lower end of the uterus is narrowed or tightened. It complicates the insertion of a tube (catheter).
- Adhesions or large fibroids. These growths sometimes block the flow of saline fluid into the uterus.

Patients with active **pelvic inflammatory disease** (PID) should not be tested with hysterosonography until the disease is brought under control. Women with chronic PID or heart problems are given **antibiotics** before the procedure.

Description

A hysterosonography is preceded by a baseline ultrasound examination performed through the vagina. This allows the doctor to detect an unsuspected **pregnancy** and to assess the thickness and possible abnormalities of the patient's endometrium. The doctor then inserts a catheter into the uterus and injects sterile saline fluid while ultrasound imaging is recorded on film or videotape. The procedure takes about 10–15 minutes.

Preparation

Patients do not require special preparation apart from the timing of the procedure. Patients with fertility problems are examined during the first 10 days of the menstrual cycle. Patients who may have polyps are usually examined at a later phase in the cycle. The best time for examining women with fibroids is still under discussion.

WWW.BOOKBAZ.IR

Aftercare

Aftercare consists of advising the patient to contact her doctor in case of abnormal bleeding, **fever**, or abdominal **pain**. Some spotting or cramping is common, and can usually be treated with **nonsteroidal anti-inflammatory drugs**, such as ibuprofen.

Risks

The chief risks are mild spotting and cramping after the procedure.

Results

Normal findings include a symmetrical uterus with a normal endometrium and no visible masses or tumors.

Abnormal results

Abnormal findings include **adhesions**; polyps; leiomyomas; abnormal thickening of the endometrium; or tissue changes related to tamoxifen (Nolvadex), which is a drug given for **breast cancer**.

Ichthyosis

Definition

Derived from two Greek words meaning "fish" and "disease," ichthyosis is a congenital (meaning present at birth) dermatological (skin) disease that is represented by thick, scaly skin.

Description

The ichthyoses are a group of skin diseases caused by an abnormality in skin growth that results in drying and scaling. There are at least 20 types of ichthyosis. Ichthyosis can be more or less severe, sometimes accumulating thick scales and cracks that are painful and bloody. Ichthyosis is not contagious. Some forms of ichthyosis are inherited while others are acquired in later life as a symptom of systemic disorders.

The most common form of ichthyosis, accounting for 95% of all cases of ichthyosis, is called ichthyosis vulgaris (*vulgaris* is the Latin word for "common"), and occurs in approximately one person in every 250. It is inherited in an autosomal dominant manner. The most rare types of ichthyosis occur in fewer than one person in one million and are inherited in an autosomal recessive manner. Ichthyosis occurs regardless of the part of the world the child is from, or the ethnic background of the parents.

Acquired ichthyosis is extremely rare; neither its incidence in the United States nor its incidence in the rest of the world are known.

Both inherited and acquired ichthyoses affect males and females equally.

Causes and symptoms

Inherited ichthyoses

Depending on the specific type of ichthyosis, the inheritance can be autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, or sporadic. Autosomal recessive means that the altered gene for the disease or trait is located on one of the first 22 pairs of chromosomes, which are also called "autosomes." Males and females are equally likely to have an autosomal recessive disease or trait. Recessive means that two copies of the altered gene are necessary to express the condition. Therefore, a child inherits one copy of the altered gene from each parent, who are called carriers (because they have only one copy of the altered gene). Since carriers do not express the altered gene, parents usually do not know they carry the altered gene that causes ichthyosis until they have an affected child. Carrier parents have a 1-in-4 chance (or 25%) with each **pregnancy**, to have a child with ichthyosis.

Autosomal dominant inheritance also means that both males and females are equally likely to have the disease but only one copy of the altered gene is necessary to have the condition. An individual with ichthyosis has a 50/50 chance to pass the condition to his or her child.

The skin is made up of several layers, supported underneath by a layer of fat that is thicker or thinner depending on location. The lower layers contain blood vessels, the middle layers contain actively growing cells, and the upper layer consists of dead cells that serve as a barrier to the outside world. This barrier is nearly waterproof and highly resistant to infection. Scattered throughout the middle layers are hair follicles, oil and sweat glands, and nerve endings. The upper layer is constantly flaking off and being replaced from beneath by new tissue. In ichthyosis, the skin's natural shedding

WWW.BOOKBAZ.IR

process is slowed or inhibited; and in some types, skin cells are produced too rapidly.

The abnormality in skin growth and hydration called ichthyosis may present with symptoms at birth or in early childhood. Ichthyosis can itch relentlessly, leading to such complications of scratching as lichen simplex (**dermatitis** characterized by raw patches of skin). Either the cracking or the scratching can introduce infection, bringing with it discomfort and complications.

Acquired ichthyoses

The mildest form of acquired ichthyosis is called xeroderma, or dry flaky skin. It is not associated with any systemic diseases. Xeroderma occurs most often on the lower legs of middle-aged and elderly adults during cold weather, or on the lower legs of people who bathe too often. It is characterized chiefly by mild or moderate **itching**.

Ichthyosis may also be an early symptom of such disorders as **AIDS**, lymphoma, **hypothyroidism**, or **leprosy**. In these cases the ichthyosis is most noticeable on the patient's trunk and legs.

A few rare cases of acquired ichthyosis have been attributed to the use of certain drugs, specifically cimetidine (Tagamet), triparanol (Metasqualene), dixyrazine (a phenothiazine derivative used as an antipsychotic), nicotinic acid (vitamin B_3), butyrophenone antipsychotics (Haldol, Inapsine, Orap), and clofazimine (Lamprene).

Diagnosis

A dermatologist will often make the diagnosis of ichthyosis based on findings from a clinical examination. However, a **skin biopsy**, or DNA study (from a small blood sample) is necessary to confirm the diagnosis. Evaluation for associated problems is done by a complete physical medical examination.

For some types of ichythyosis, the abnormal gene has been identified and prenatal testing is available. At present this is true for the autosomal recessive congenital ichythoses, which include: lamellar ichthyosis (LI), autosomal recessive lamellar ichthyosis (ARLI), congenital ichthyosiform erythroderma (CIE), and non-bullous congenital ichthyosiform erythroderma (NBCIE).

There are four different genes that have been located for the autosomal recessive congenital ichthyoses. Testing, however, is available for only one gene, known as transglutaminase-1 (TGM1). This gene is located on chromosome 14. Once a couple has had a child with ichthyosis, and they have had the genetic cause identified by DNA studies (performed from a small blood sample), prenatal testing for future pregnancies may be considered. (prenatal testing may not be possible if both mutations cannot be identified.) Prenatal diagnosis is available via either **chorionic villus sampling** (CVS) or **amniocentesis**. CVS is a biopsy of the placenta performed in the first trimester of pregnancy under **ultrasound** guidance. Ultrasound is the use of sound waves to visualize the developing fetus. The genetic makeup of the placenta is identical to the fetus and, therefore, the TGM1 gene can be studied from this tissue. There is approximately a one in 100 chance for **miscarriage** with CVS. Amniocentesis is a procedure done under ultrasound guidance in which a long thin needle is inserted through the mother's abdomen into the uterus, to withdraw a couple of tablespoons of amniotic fluid (fluid surrounding the developing baby) to study. The TGM1 gene can be studied using cells from the amniotic fluid. Other genetic tests, such as a chromosome analysis, may also be performed through either CVS or amniocentesis.

Acquired ichthyosis is usually diagnosed in the course of identifying the underlying disorder. With the exception of acquired ichthyosis related to lymphoma, a doctor cannot tell the difference between inherited and acquired ichthyosis by examining skin samples through a microscope.

Treatment

Most treatments for ichthyosis are topical, which means that they are applied directly to the skin, not taken internally. Xeroderma is eaily treated by minimizing bathing and applying an emollient cream or mineral oil after bathing while the skin is still moist. Some forms of ichthyosis require two forms of treatment—a reduction in the amount of scale buildup and moisturizing of the underlying skin. Several agents are available for each purpose. Reduction in the amount of scale is achieved by keratolytics. Among this class of drugs are urea, lactic acid, and salicylic acid. Petrolatum, 60% propylene glycol, and glycerin are successful moisturizing agents, as are many commercially available products. Increased humidity of the ambient air is also helpful in preventing skin dryness.

Because the skin acts as a barrier to the outside environment, medicines have a hard time penetrating, especially through the thick skin of the palms of the hands and the soles of the feet. This resistance is diminished greatly by maceration (softening the skin). Soaking hands in water macerates skin so that it looks like prune skin. Occlusion (covering) with rubber gloves or plastic wrap will also macerate skin.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive inheritance—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Dermatologist—A physician who specializes in diagnosing and treating disorders of the skin.

Emollients—Petroleum or lanolin-based skin lubricants.

Keratin—A tough, nonwater-soluble protein found in the nails, hair, and the outermost layer of skin. Human hair is made up largely of keratin.

Keratinocytes—Skin cells.

Keratolytic—An agent that dissolves or breaks down the outer layer of skin (keratins).

Retinoids—A derivative of synthetic Vitamin A.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

X-linked dominant inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male or female, passed from an affected female who has the gene on one of her X chromosomes.

X-linked recessive inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes, and who is referred to as an unaffected carrier.

Applying medicines and then covering the skin with an occlusive dressing will facilitate entrance of the medicine and greatly magnify its effect.

Secondary treatments are necessary to control pruritus (itching) and infection. Commercial products containing camphor, menthol, eucalyptus oil, aloe, and similar substances are very effective as antipruritics. If the skin cracks deeply enough, a pathway for infection is created. **Topical antibiotics** like bacitracin are effective in prevention and in the early stages of these skin infections. Cleansing with hydrogen peroxide inhibits infection as well.

Finally, there are topical and internal derivatives of **vitamin A** called retinoids that improve skin growth and are used for severe cases of **acne**, ichthyosis, and other skin conditions. Tazarotene (Tazorac), a retinoid that was originally developed to treat **psoriasis** and acne, appears to give good results in treating ichthyosis with fewer side effects than other retinoids.

Prognosis

This condition requires continuous care throughout a lifetime. Properly treated, in most cases it is a cosmetic problem. There are a small number of lethal forms, such as harlequin fetus.

Idiopathic thrombocytopenic purpura

Definition

Idiopathic thrombocytopenic purpura, or ITP, is a bleeding disorder caused by an abnormally low level of platelets in the patient's blood. Platelets are small plate-shaped bodies in the blood that combine to form a plug when a blood vessel is injured. The platelet plug then binds certain proteins in the blood to form a clot that stops bleeding. ITP's name describes its cause and two symptoms. Idiopathic means that the disorder has no apparent cause. ITP is now often called immune thrombocytopenic purpura rather than idiopathic because of recent findings that ITP patients have autoimmune antibodies in their blood. **Thrombocytopenia** is another word for a decreased number of blood platelets. Purpura refers to a purplish or reddish-brown skin rash caused by the leakage of blood from broken capillaries into the skin. Other names for ITP include purpura hemorrhagica and essential thrombocytopenia.

Demographics

ITP may be either acute or chronic. The acute form is most common in children between the ages of one and six years; the chronic form is most common in adult females between 30 and 40. ITP is uncommon in adults older than age 60. Between 10% and 20% of children with ITP have the chronic form. ITP does not appear to be related to race, lifestyle, climate, or environmental factors.

In the United States, annual incidence of ITP is difficult to determine because it is thought that most cases of ITP are so mild that medical attention is not needed. Estimates are that ITP affects 5 in every 100,000 children and 2 in every 100,000 adults in the United States every year.

Description

ITP is a disorder that affects the overall number of blood platelets rather than their function. The normal platelet level in adults is between 150,000 and 450,000/mm^3. Platelet counts below 50,000 mm^3 increase the risk of dangerous bleeding from **trauma**; counts below 20,000/mm^3 increase the risk of spontaneous bleeding.

Causes and symptoms

In adults, ITP is considered an autoimmune disorder, which means that the body produces antibodies that damage some of its own products—in this case, blood platelets. Some adults with chronic ITP also have other immune system disorders, such as **systemic lupus erythematosus** (SLE) or acute or chronic leukemia. ITP is usually triggered by a viral infection such as infection with **rubella**, **chickenpox**, **measles**, cytomegalovirus, **Epstein-Barr virus**, or hepatitis virus (A, B, C). It usually begins about two or three weeks after the infection. ITP may also occur as a result of infection with the human **immunodeficiency** virus (HIV). Most commonly, ITP follows a viral upper respiratory infection or **gastroenteritis**.

Some medications are also linked to the development of ITP. These medications include:

- quinidine or quinine medications
- heparin
- antibiotics such as cephalosporin drugs and rifampicin
- analgesics
- diuretics
- antihypertensives

ITP is also associated with acute and chronic alcohol ingestion and is seen in individuals with chronic **liver disease**.

In children, most cases of ITP are acute while in adults, most cases are chronic.

Acute ITP

Acute ITP is characterized by bleeding into the skin or from the nose, mouth, digestive tract, or urinary tract. The onset is usually sudden. Bleeding into the skin takes the form of purpura or petechiae. Purpura is a purplish or reddish-brown rash or discoloration of

KEY TERMS

Autoimmune disorder—A disorder in which the patient's immune system produces antibodies that destroy some of the body's own products. ITP in adults is thought to be an autoimmune disorder.

Idiopathic—Of unknown cause. Idiopathic refers to a disease that is not preceded or caused by any known dysfunction or disorder in the body.

Petechiae—Small pinpoint hemorrhages in skin or mucous membranes caused by the rupture of capillaries.

Platelet—A blood component that helps to prevent blood from leaking from broken blood vessels. ITP is a bleeding disorder caused by an abnormally low level of platelets in the blood.

Prednisone—A corticosteroid medication used to treat ITP. Prednisone works by decreasing the effects of antibody on blood platelets. Long-term treatment with prednisone is thought to decrease antibody production.

Purpura—A skin discoloration of purplish or brownish red spots caused by bleeding from broken capillaries.

Splenectomy—Surgical removal of the spleen.

Thrombocytopenia—An abnormal decline in the number of platelets in the blood.

the skin; petechiae are small round pinpoint hemorrhages. Both are caused by the leakage of blood from tiny capillaries under the skin surface. In addition to purpura and petechiae, the patient may notice that he or she **bruises** more easily than usual. In extreme cases, patients with ITP may bleed into the lungs, brain, or other vital organs.

Chronic ITP

Chronic ITP has a gradual onset and may have minimal or no external symptoms. The low **platelet count** may be discovered in the course of a routine blood test. Most patients with chronic ITP will consult their primary care doctor because of the purpuric skin rash, nosebleeds, or bleeding from the digestive or urinary tract. Women sometimes go to their gynecologist for unusually heavy or lengthy menstrual periods.

Diagnosis

ITP is usually considered a diagnosis of exclusion, which means that the doctor arrives at the diagnosis by a process of ruling out other possible causes. If the patient belongs to one or more of the risk groups for chronic ITP, the doctor may order a blood test for autoantibodies in the blood early in the diagnostic process.

Physical examination

If the doctor suspects ITP, he or she will examine the patient's skin for bruises, purpuric areas, or petechiae. If the patient has had nosebleeds or bleeding from the mouth or other parts of the body, the doctor will examine these areas for other possible causes of bleeding. Patients with ITP usually look and feel healthy except for the bleeding.

The most important features that the doctor will be looking for during the **physical examination** are the condition of the patient's spleen and the presence of **fever**. Patients with ITP do not have fever, whereas patients with lupus and some other types of thrombocytopenia are usually feverish. The doctor will have the patient lie flat on the examining table in order to feel the size of the spleen. If the spleen is noticeably enlarged, ITP is usually excluded as the diagnosis.

Laboratory testing

The doctor will order a **complete blood count** (CBC), a test of clotting time, a bone marrow test, and a test for antiplatelet antibodies if it is available in the hospital laboratory. Patients with ITP usually have platelet counts below 20,000/mm^3 and prolonged **bleeding time**. The size and appearance of the platelets may be abnormal. The red blood cell count (RBC) and **white blood cell count** (WBC) are usually normal, although about 10% of patients with ITP are also anemic. The blood marrow test yields normal results. Detection of antiplatelet antibodies in the blood is considered to confirm the diagnosis of ITP.

In most children, examination of the bone marrow is not required to diagnose acute ITP.

Treatment

General care and monitoring

There is no specific treatment for ITP. In most cases, the disorder will resolve without medications or surgery within two to six weeks. Nosebleeds can be treated with ice packs when necessary.

WWW.BOOKBAZ.IR

General care includes explaining ITP to the patient and advising him or her to watch for bruising, petechiae, or other signs of recurrence. Children should be discouraged from rough contact sports or other activities that increase the risk of trauma. Patients are also advised to avoid using **aspirin** or ibuprofen (Advil, Motrin) as **pain** relievers because these drugs lengthen the clotting time of blood.

Treatment with **corticosteroids** such as oral prednisone or IV methylprednisone are the initial drugs of choice for the treatment of ITP.

Emergency treatment

Patients with acute ITP who are losing large amounts of blood or bleeding into their central nervous system require emergency treatment. This includes transfusions of platelets, intravenous immunoglobulins, or treatment with corticosteroids such as methylprednisone. Prednisone is a steroid medication that decreases the effects of antibody on platelets and eventually lowers antibody production. If the patient has a history of ITP that has not responded to prednisone or immunoglobulins, the surgeon may remove the patient's spleen. This operation is called a **splenectomy**. The reason for removing the spleen when ITP does not respond to other forms of treatment is that the spleen sometimes keeps platelets out of the general blood circulation.

Medications and transfusions

Patients with chronic ITP can be treated with prednisone, immune globulin, or large doses of intravenous **gamma globulin**. Although 90% of patients respond to immunoglobulin treatment, it is very expensive. About 80% of patients respond to prednisone therapy. Platelet transfusions are not recommended for routine treatment of ITP. If the patient's platelet level does not improve within 1–4 months, or requires high doses of prednisone, the doctor may recommend splenectomy. All medications for ITP are given either orally or intravenously; intramuscular injection is avoided because of the possibility of causing bleeding into the skin.

Newer medications that may be used in the treatment of ITP include the monoclonal antibody rituximab (Rituxan), which can be combined with the corticosteroid dexamethasone to treat chronic ITP and thrombopoietin-receptor agonists romiplostim (Nplate) and eltrombopag (Promacta), which work by directly stimulating the bone marrow to increase platelet production.

Surgery

Between 80% and 85% of adults with ITP have a remission of the disorder after the spleen is removed. Splenectomy is usually avoided in children younger than five years because of the increased risk of a severe infection after the operation. In older children, however, splenectomy is recommended if the child has been treated for 12 months without improvement; if the ITP is very severe or the patient is getting worse; if the patient begins to bleed into the head or brain; and if the patient is an adolescent female with extremely heavy periods. Relapse of ITP is more common after splenectomy in patients with chronic ITP as compared to those with acute ITP.

Prognosis

The prognosis for recovery from acute ITP is good; 80% of patients recover without special treatment. The prognosis for chronic ITP is also good; most patients experience long-term remissions. In rare instances ITP can cause life-threatening hemorrhage or bleeding into the central nervous system.

Prevention

In most individuals, ITP occurs as a manifestation of another disease or as a consequence of a viral infection. Therefore, at this time ITP cannot be entirely prevented.

Ileal conduit *see* **Ileal conduit surgery**

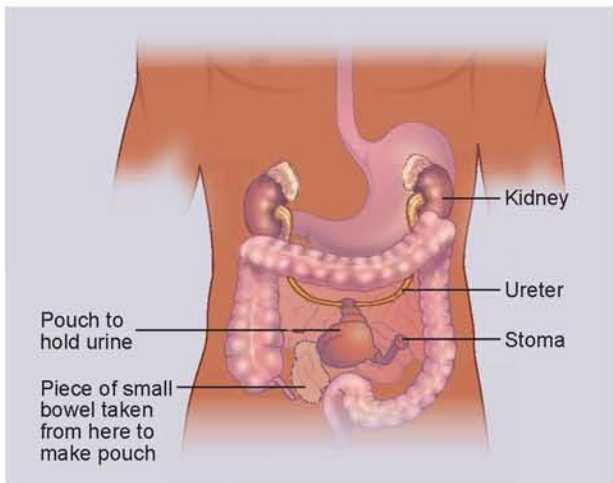
Ileal conduit surgery

Definition

There are many surgical techniques for **urinary diversion surgery**. They fall into two categories: continent diversion and conduit diversion. In continent diversion, also known as continent catheterizable stomal reservoir, a separate rectal reservoir for urine is created, which allows evacuation from the body. In conduit diversion, or orthotopic urethral anastomotic procedure, an intestinal stoma or conduit for release of urine is created in the abdominal wall so that a catheter or **ostomy** can be attached for the release of urine. An ileal conduit is a small urine reservoir that is surgically created from a small segment of bowel. Both techniques are forms of **reconstructive surgery** to replace the bladder or bypass obstructions or disease in the bladder so that urine can pass out of the body. Both procedures have been used for years and should be considered for all appropriate patients. Ileal conduit surgery, the easiest of the reconstructive surgeries, is the gold standard by which other surgical techniques, both continent and conduit, have been compared as the techniques have advanced over the decades.

Purpose

The bladder creates a reservoir for the liquid wastes created by the kidneys as a result of the ability of these organs to filter and retain glucose, salts, and **minerals** that the body needs. When the bladder must be removed; or becomes diseased, injured, obstructed, or develops leak points; the release of urinary wastes from the kidneys becomes impaired, endangering the kidneys with an overburden of poisons. Reasons for disabling the urinary bladder are: cancer of the bladder; neurogenic sources of bladder dysfunction; bladder sphincter detrusor overactivity that causes continual urge incontinence; chronic inflammatory diseases of the bladder; **tuberculosis**; and **schistosomiasis**, which is an infestation of the bladder by parasites, mostly occurring Africa and Asia. Radical **cystectomy**, removal of the bladder, is the predominant treatment for cancer of the bladder, with radiation and **chemotherapy** as other alternatives. In both cases, urinary diversion is often necessitated, either due to the whole or partial removal of the bladder or to damage done by radiation to the bladder.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Demographics

Urinary diversion has a long history and, over the last two decades, has developed new techniques for urinary tract reconstruction to preserve renal function and to increase the quality of life. A number of difficulties had to be solved for such progress to take place. Clean intermittent catheterization by the patient became possible in the 1980s, and many patients with loss of bladder function were able to continue to have urine release through the use of catheters. However, it soon became clear that catheterization left a residue that cumulatively, and over time, increased the risk of infection, which subsequently decreased kidney function through reflux, or backup, of urine into the kidneys. A new way had to be found. With the advent of surgical anastomosis (the grafting of vascularizing tissue for the repair and expansion of organ function) as well as with the ability to include a flap-type of valve to prevent backup, bladder reconstructive surgery that allowed for protection of the kidneys became possible.

Description

Surgery is performed by a urological surgeon who specializes in urinary diversion. It is performed in a general hospital.

Ileal conduit surgery consists of open abdominal surgery. The surgeon first isolates the ileum, which is the last section of small bowel. The segment used is about 5.9–7.8 in. (15–20 cm) in length. It is anastomosed, or grafted, to the ureters with absorbable sutures. A stoma, or opening in skin, is created on the right side of the abdomen, and the other end of the bowel segment is attached to the stoma, which drains into an ostomy bag.

Stents are used to bypass the surgical site and divert urine externally, ensuring that the anastomotic

WWW.BOOKBAZ.IR

KEY TERMS

Neobladder—A term that refers to the creation of a reservoir for urine made from intestinal tissue that allows for evacuation.

Ostomy—A pouch attached to an outlet through the abdominal wall that allows urine to drain and be collected after the surgical removal of the bladder.

Stoma—A term used for the opening in the abdomen created to reroute urine to an external collection pouch, or ostomy.

Urinary conduit diversion—A type of urinary diversion or rerouting that uses a conduit made from an intestinal segment to channel urine to an outside collection pouch.

site has adequate healing time. Continent surgeries are more extensive than the ileal conduit surgery. Both types of surgery require an extensive hospitalization with careful monitoring of the patient for infections, removal of stents placed in the bowel during surgery, and removal of catheters.

Preparation

Ileal conduit surgery is recommended depending on what conditions are being treated; whether the urinary diversion is immediately necessary; for the relief of **pain** or discomfort; or for relatively healthy individuals or individuals with terminal illness. Three major decisions must be made by the physician and patient:

1. the type of surgery used to restore bladder function—either sending urine through the ureters to a new repository fashioned in the rectum, or creating a conduit for the removal of the urine out through the stomach wall and into a permanent storage pouch or ostomy outside the body
2. the type of material out of which to fashion the reservoir or conduit
3. where to place the stoma outlet for patient use

Recent research has shown there is little difference in infection rates or in renal deterioration between the conduit surgical techniques and the continent techniques. The patient's preference becomes important as to which type of surgery and resulting procedures for urination they want. Of course, some patients, unable to conduct catheterization due to debilitating diseases like **multiple sclerosis** or neurological injuries, should be encouraged to have the reservoir or continent procedures.

Materials for fashioning continent channels have included sections of the appendix, stomach, ileum and cecum of the intestines, and for the reservoir, sigmoid and ureter tissues, usually with an antirefluxing mechanism to maximize continence. A segment of the ileum is often preferred, unless the tissue has received radiation. In this case, other tissue must be used. Ileum is preferred because the ileal tissue of the intestines accommodates larger urine volume at a lower pressure.

Many urinary diversion procedures are performed in conjunction with surgery for recurrent cancer or complications of pelvic radiation. **Fistula** development and repeated repair as well as ureteral obstruction also are reasons to have the surgery. If the surgery is considered because of cancer, the physician and the patient need to discuss how appropriate the surgery is for providing a cure or for relieving pain. Highly relevant are the patient's age, medical condition, and ability to comprehend both the procedure and the patient's role in the changed state that will result with the surgery. In general, ileal conduit surgery is easier, faster, and has fewer complications than continent reservoir surgery.

In addition to these considerations, great emphasis must be put on preparing the patient psychologically, and physicians must make themselves available for counseling and questions before proceeding with patient evaluation for the procedures. The renal system must be assessed using pyelography, which is the visualization of the renal pelvis of the kidneys to determine the health of each renal system. Patients with renal disease or abnormalities are not good candidates for urinary diversion. **Bowel preparation** and prophylactic **antibiotics** are necessary to avoid infection with the surgery. Bowel preparation includes injecting a clear-liquid diet preoperatively for two days, followed by a cleansing enema or **enemas** until the bowel runs clear. The importance of these preparations must be explained to the patient: leaking from the bowel during surgery can be life threatening. For ileal conduits, the placement of the stoma must be decided. This is accomplished after the physician evaluates the patient's abdomen in both a sitting and standing position, to avoid placing the stoma in a fatty fold of the abdomen. The input from a stomal therapist is important for this preparation with the patient.

Aftercare

Ureteral stents are generally removed one week after surgery. A **urine culture** is taken from each stent. Radiologic contrast studies are carried out to ensure against ureteral anastomotic leakage or obstruction. On the seventh postoperative day, a contrast study is performed to ensure pouch integrity. Thereafter,

ureteral stents may be removed, again with radiologic control. When it has been determined that the ureteral anastomoses and pouch are intact, the suction drain is removed. The patient is shown how to support the operative site when sleeping and with breathing and coughing. Fluids and electrolytes are infused intravenously until the patient can take liquids by mouth. The patient is usually able to get up in eight to 24 hours and leave the hospital in about a week.

Patients are taught how to care for the ostomy, and family members are educated as well. Appropriate supplies and a schedule of how to change the pouch are discussed, along with skin care techniques for the area surrounding the stoma. Often, a stomal therapist will make a home visit after discharge to help the patient return to normal daily activities.

Risks

This surgery includes the major risks of thrombosis and heart difficulties that can result from abdominal surgery. Many difficulties can occur after urinary diversion surgery, including urinary leakage, problems with a stoma, changes in fluid balance, and infections over time. However, urinary diversion is usually tolerated well by most patients, and reports indicate that patient satisfaction is very high. Common complications are stricture caused by inflammation or scar tissue from surgery, disease, or injury. The incidence of urine leakage for all types of ureterointestinal anastomoses is 3–5% and occurs within the first 10 days after surgery. According to some researchers, this incidence of leakage can be reduced to near zero if stents are used during surgery.

Results

Complete healing is expected without complications, with the patient returning to normal activities once they have recovered from surgery.

Morbidity and mortality rates

Possible complications associated with ileal conduit surgery include bowel obstruction, **blood clots**, **urinary tract infection**, **pneumonia**, skin breakdown around the stoma, stenosis of the stoma, and damage to the upper urinary tract by reflux. **Pyelonephritis**, or bacterial infection of a kidney, occurs both in the early postoperative period and over the long term. Approximately 12% of patients diverted with ileal conduits and 13% in those diverted with antirefluxing colon conduits have this complication. Pyelonephritis is associated with significant mortality.

Alternatives

An alternative to ileal conduit surgery is continent surgery in which a neobladder is fashioned from bowel segments, allowing the patient to evacuate the urine and avoid having an external appliance. The procedures of continent diversion are more complicated, require more hospitalization, and have higher complication rates than conduit surgery. Many patients, unable to manage a stoma, are good candidates for continent diversion.

Ileus

Definition

Ileus is a partial or complete non–mechanical blockage of the small and/or large intestine. When this blockage occurs the bowel becomes full of gases and fluids. Consequently, patients often report mild abdominal **pain** and bloating. They may also experience poor appetite, nausea, and, sometimes, **vomiting**. The term "ileus" comes from the Latin word for **colic**. Ileus is sometimes also called bowel obstruction, intestinal volvulus, colonic ileus, and other such terms.

Demographics

The blockage of the intestines from the condition called ileus can occur at any age. In infants and children, it is the major cause of bowel obstruction. In adults, abdominal surgery can often bring about ileus. It occurs throughout the human population, regardless of one's ethnic background or other factors.

Description

There are two types of **intestinal obstructions** (when the bowel does not work correctly), mechanical and non–mechanical. Mechanical obstructions occur because the bowel is physically (structurally) blocked and its contents cannot pass the point of the obstruction. This happens when the bowel twists on itself (volvulus) or as the result of hernias, impacted feces, abnormal tissue growth, or the presence of foreign bodies in the intestines.

Unlike mechanical obstruction, non–mechanical obstruction, called ileus or paralytic ileus, occurs when there is not a structural problem within the bowel but, instead, because peristalsis stops. Peristalsis is the rhythmic contraction that moves material through the bowel. Thus, ileus occurs when the muscles of the bowel wall have failed, and they are unable to transport contents through the intestinal tract. Ileus is most often associated with an infection of the peritoneum (the membrane lining the abdomen). It is one of the major causes of bowel obstruction in infants and children.

Another common cause of ileus is a disruption or reduction of the blood supply to the abdomen. Handling the bowel during abdominal surgery can also cause peristalsis to stop, a condition known as postoperative ileus. People who have had abdominal surgery are more likely to experience ileus. The condition is often temporary and usually lasts 48–72 hours.

Ileus sometimes occurs as a complication of surgery on other parts of the body, including joint replacement or chest surgery.

Ileus can be caused by kidney diseases, especially when potassium levels decrease; by **heart disease**; and certain **chemotherapy** drugs such as vinblastine (Velban, Velsar) and vincristine (Oncovin, Vincasar PES, Vincrex). Infants with **cystic fibrosis** are more likely to experience meconium ileus (a dark green material in the intestine). Over all, the total rate of bowel obstruction due both to mechanical and non–mechanical causes is one in 1,000 people.

Causes and symptoms

The major cause of ileus is operations occurring within and about the intestines. Normal activity of the intestines usually returns within hours to days after such operations. Other causes of ileus include:

- drugs, such as antacids, chlorpromazine, opioids, warfarin, and amitriptline
- metabolic changes, such as those caused by low levels of iron, potassium magnesium, or sodium
- pneumonia
- heart attack (myocardial infarction)
- trauma, such as injuries to the head and spinal column
- pneumonia

When the bowel stops functioning, the following symptoms can occur:

- abdominal cramping
- abdominal distension, discomfort, and tenderness
- poor appetite
- nausea and vomiting, especially after eating

KEY TERMS

Bowel—The part of the intestines that is connected to the anus.

Computed tomography scan (or CT scan)—A computer enhanced x-ray study performed to detect abnormalities that do not show up on normal x rays.

Meconium—A greenish fecal material that forms the first bowel movement of an infant.

Peritoneum—The transparent membrane lining the abdominal cavity that holds internal organs in place.

- excessive belching
- constipation
- failure to pass gas (flatulence) or to have a bowel movement (defecation)
- absence of abdominal cramping

Diagnosis

When a doctor listens with a stethoscope to the abdomen, there will be few or no bowel sounds, indicating that the intestine has stopped functioning. Ileus can be confirmed by x rays of the abdomen, **computed tomography scans** (CT scans), or **ultrasound**. It may be necessary to do more invasive tests, such as a **barium enema** or upper gastrointestinal (GI) series, if the obstruction is mechanical. Blood tests also are useful in diagnosing paralytic ileus.

Barium studies are used in cases of mechanical obstruction, but may cause problems by increasing pressure or intestinal contents if used in ileus. Also, in cases of suspected mechanical obstruction involving the gastrointestinal tract (from the small intestine downward) use of barium x rays are contraindicated, since they may contribute to the obstruction. In such cases a barium enema should always be performed first.

Treatment

Patients may be treated with supervised bed rest in a hospital and bowel rest. Bowel rest means that nothing is taken by mouth and patients are fed intravenously or through the use of a **nasogastric tube**. (A nasogastric tube provides relief for patients with vomiting and distension; however, it has not been found helpful with treating ileus itself.) A nasogastric tube is a tube inserted through the nose, down the throat, and into the stomach. A similar tube can be inserted in the intestine. The contents are then suctioned out. In some cases, especially where there is a mechanical obstruction, surgery may be necessary.

Narcotics are often used after surgery for pain relief but can be replaced over time with nonsteroidal anti–inflammatory drugs (NSAIDs), which also help with reducing inflammation. Drug therapies that promote intestinal motility (ability of the intestine to move spontaneously), such as cisapride (Prepulsid, Propulsid) and vasopressin (Pitressin), are sometimes prescribed.

Alternatives

Alternative practitioners offer few treatment suggestions, but focus on prevention by keeping the bowels healthy through eating a good diet that is high in fiber and low in fat. If the case is not a medical emergency, homeopathic treatment and **traditional Chinese medicine** can recommend therapies that may help to reinstate peristalsis.

Prognosis

The outcome of ileus varies depending on its cause. Complications may occur, including infection, **jaundice** (yellow skin discoloration), perforation (hole) in the intestine, or electrolyte imbalances (any of a number of free–ion substances in the body that are not in normal concentrations).

Prevention

Most cases of ileus are not preventable. Surgery to remove a tumor or other mechanical obstruction will help prevent a recurrence.

Some measures that have been recommended to minimize the severity of postoperative ileus or shorten its duration include making sure that any electrolyte imbalances are corrected, and using non-opioid medications to relieve pain, as opioid drugs (including morphine, oxycodone, and codeine) tend to cause **constipation**. One group of drugs that shows promise for treating abdominal pain is a class of medications known as kappa–opioid agonists. As of 2014, these drugs are still under investigation for controlling visceral pain in humans. Further clinical studies are needed to determine their ability to treat such pain.

Immobilization

Definition

Immobilization refers to the process of holding a joint or bone in place with a splint, cast, or brace. This is done to prevent an injured area from moving while it heals.

Description

When an arm, hand, leg, or foot requires immobilization, the cast, splint, or brace will generally extend from the joint above the injury to the joint below the injury. For example, an injury to the mid-calf requires immobilization from the knee to the ankle and foot. Injuries of the hip and upper thigh or shoulder and upper arm require a cast that encircles the body and extends down the injured leg or arm.

Casts are generally used for immobilization of a broken bone. Once the doctor makes sure the two broken ends of the bone are aligned, a cast is put on to keep them in place until they are rejoined through natural healing. Casts are applied by a physician, a nurse, or an assistant. They are custom-made to fit each person, and are usually made of plaster or fiberglass. Fiberglass weighs less than plaster, is more durable, and allows the skin more adequate airflow than plaster. A layer of cotton or synthetic padding is first wrapped around the skin to cover the injured area and protect the skin. The plaster or fiberglass is then applied over this.

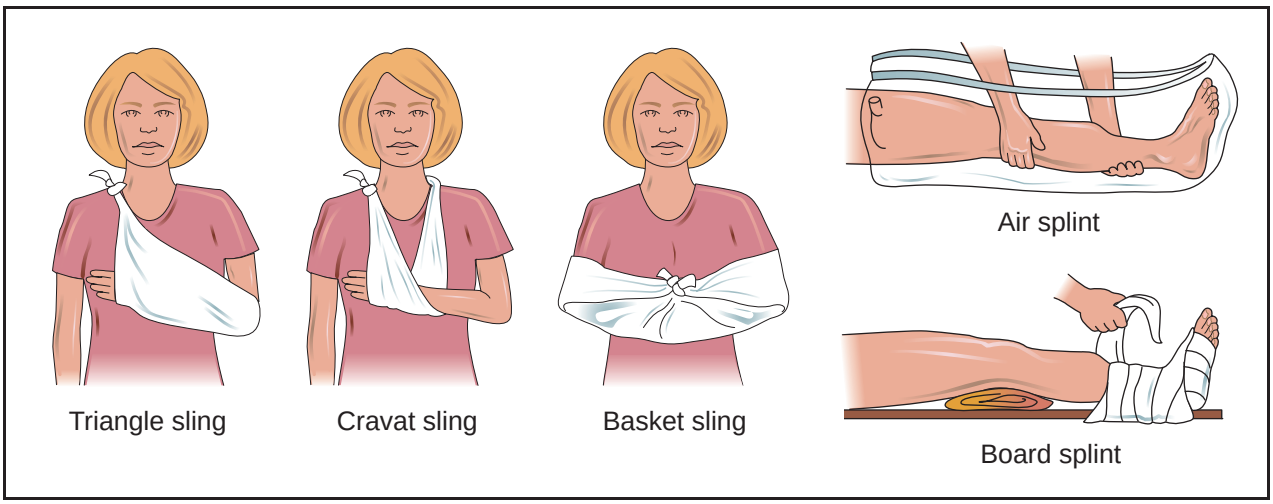
Most casts should not be gotten wet. However, some types of fiberglass casts use Gore-tex padding that is waterproof and allows the person to completely immerse the cast in water when taking a shower or bath. There are some circumstances when this type of cast material can not be used.

A splint is often used to immobilize a dislocated joint while it heals. Splints are also often used for finger injuries, such as **fractures** or baseball finger. Baseball finger is an injury in which the tendon at the end of the finger is separated from the bone as a result of **trauma**. Splinting also is used to immobilize an injured arm or leg immediately after an injury. Before moving a person who has injured an arm or leg some type of temporary splint should be applied to prevent further injury to the area. Splints may be made of acrylic, polyethylene foam, plaster of paris, or aluminum. In an emergency, a splint can be made from a piece of wood or rolled magazine.

Slings are often used to support the arm after a fracture or other injury. They are generally used along with a cast or splint, but sometimes are used alone as a means of immobilization. They can be used in an emergency to immobilize the arm until the person can be seen by a doctor. A triangular bandage is placed under the injured arm and then tied around the neck.

Braces are used to support, align, or hold a body part in the correct position. Braces are sometimes used after a surgical procedure is performed on an arm or leg. They can also be used for an injury. Since some braces can be easily taken off and put back on, they are often used when the person must have **physical therapy** or **exercise** the limb during the healing process. Many braces can also be adjusted to allow for a certain amount of movement.

Braces can be custom-made, or a ready-made brace can be used. Off-the-shelf braces are made in a variety of shapes and sizes. They generally have Velcro straps that make the brace easy to adjust, and to put



Immobilization refers to the process of immobilizing or fixating the position of a joint, bone, extremity, or torso with a splint, cast, or brace. Immobilization can help reduce pain, swelling, and muscle spasms. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

on and take off. Both braces and splints offer less support and protection than a cast and may not be a treatment option in all circumstances.

A collar is generally used for neck injuries. A soft collar can relieve **pain** by restricting movement of the head and neck. They also transfer some of the weight of the head from the neck to the chest. Stiff collars are generally used to support the neck when there has been a fracture in one of the bones of the neck. Cervical collars are widely used by emergency personnel at the scene of injuries when there is a potential neck or **head injury**.

Immobilization may also be secured by **traction**. Traction involves using a method for applying tension to correct the alignment of two structures (such as two bones) and hold them in the correct position. For example, if the bone in the thigh breaks, the broken ends may have a tendency to overlap. Use of traction will hold them in the correct position for healing to occur. The strongest form of traction involves inserting a stainless steel pin through a bony prominence attached by a horseshoe-shaped bow and rope to a pulley and weights suspended over the end of the patient's bed.

Traction must be balanced by countertraction. This is obtained by tilting the bed and allowing the patient's body to act as a counterweight. Another technique involves applying weights pulling in the opposite direction.

Traction for neck injuries may be in the form of a leather or cotton cloth halter placed around the chin and lower back of the head. For very severe neck injuries that require maximum traction, tongs that resemble ice tongs are inserted into small holes drilled in the outer skull.

All traction requires careful observation and adjustment by doctors and nurses to maintain proper balance and alignment of the traction with free suspension of the weights.

Immobilization can also be secured by a form of traction called skin traction. This is a combination of a splint and traction that is applied to the arms or legs by strips of adhesive tape placed over the skin of the arm or leg. Adhesive strips, moleskin, or foam rubber traction strips are applied on the skin. This method is effective only if a moderate amount of traction is required.

Purpose

Splints, casts, and braces support and protect broken bones, dislocated joints, and such injured soft tissue as tendons and ligaments. Immobilization restricts motion to allow the injured area to heal. It can help reduce pain, swelling, and muscle spasm. In some cases, splints and casts are applied after surgical procedures that repair bones, tendons, or ligaments. This allows for protection and proper alignment early in the healing phase.

Preparation

There are many reasons for immobilization using splints, casts, and braces. Each person should understand his or her diagnosis clearly.

WWW.BOOKBAZ.IR

KEY TERMS

Decubitus ulcers—A pressure sore resulting from ulceration of the skin occurring in persons confined to bed for long periods of time.

Ligament—Ligaments are structures that hold bones together and prevent excessive movement of the joint. They are tough, fibrous bands of tissue.

Pneumonia—An acute or chronic disease characterized by inflammation of the lungs and caused by viruses, bacteria, or other microorganisms.

Tendon—Tendons are structures that attach bones to muscles and muscles to other muscles.

Aftercare

After a cast or splint has been put on, the injured arm or leg should be elevated for 24–72 hours. It is recommended that the person lie or sit with the injured arm or leg raised above the level of the heart. Rest combined with elevation will reduce pain and speed the healing process by minimizing swelling.

Fingers or toes can be exercised as much as can be tolerated after casting. This has been found to decrease swelling and prevent stiffness. If excessive swelling is noted, the application of ice to the splint or cast may be helpful.

After the cast, splint, or brace is removed, gradual exercise is usually performed to regain muscle strength and motion. The doctor may also recommend **hydrotherapy**, **heat treatments**, and other forms of physical therapy.

Results

Normally, the surgical or injured area heals appropriately with the help of immobilization. The form of immobilization can be discontinued, which is followed by an appropriate **rehabilitation** program under the supervision of a physical therapist to regain range of motion and strength.

Risks

For some people, such as those in traction, immobilization will require long periods of bedrest. Lying in one position in bed for an extended period of time can result in sores on the skin (decubitus **ulcers**) and skin infection. Long periods of bedrest can also cause a buildup of fluid in the lungs or an infection in the lungs (**pneumonia**). Urinary infection can also be a result of extended bedrest.

People who have casts, splints, or braces on their arms or legs will generally spend several weeks not using the injured arm or leg. This lack of use can result in decreased muscle tone and shrinkage of the muscle (atrophy). Much of this loss can usually be regained through rehabilitation after the injury has healed.

Immobility can also cause psychological **stress**. An individual restricted to a bed with a traction device may become frustrated and bored, and perhaps even depressed, irritable, and withdrawn.

There is the possibility of decreased circulation if the cast, splint, or brace fits too tightly. Excessive pressure over a nerve can cause irritation or possible damage if not corrected. If the cast, splint, or brace breaks or malfunctions, the healing process of the bone or soft tissue can be disrupted and lead to deformity.

Immune complex detection *see* **Immune complex test**

Immune complex test

Definition

These tests evaluate the immune system, whose function is to defend the body against such invaders as bacteria and viruses. The immune system also plays a role in the control of cancer, and is responsible for the phenomena of allergy, hypersensitivity, and rejection problems when organs or tissue are transplanted.

One of the ways the immune system protects the body is by producing proteins called antibodies. Antibodies are formed in response to another type of protein called an antigen (anything foreign or different from a natural body protein). Immune complex

KEY TERMS

Antibody—A (immunoglobulin) molecule that interacts with a specific antigen. Antibodies provide protection from microscopic invaders like bacteria.

Antigen—Any substance that is capable under certain circumstances of producing an immune response either from antibodies or T-cells; bacteria are often antigens.

Autoimmune disorder—A disorder caused by a reaction of an individual's immune system against the organs or tissues of the body. Autoimmune processes can have different results: slow destruction of a particular type of cell or tissue, stimulation of an organ into excessive growth, or interference in function.

Biopsy—The removal and examination, usually under a microscope, of tissue from the living body. Used for diagnosis.

Systemic lupus erythematosus—A chronic disease of the connective tissues in the body; characterized by involvement of the skin, joints, kidneys, and serosal membranes (membranes that form the outer covering of organs in the abdomen or chest).

reactions occur when large numbers of antigen-antibody complexes accumulate in the body.

Purpose

The purpose of the immune complex test is to demonstrate circulating immune complexes in the blood, to estimate the severity of immune complex disease, and to monitor response to therapy.

Precautions

Because this test is requested when the physician suspects that a patient's immune system is not functioning properly, special care should be taken during and after blood is drawn. For example, the venipuncture site should be kept clean and dry to avoid any chance of infection.

Description

Immune complexes are normally not detected in the blood. However, when immune complexes are produced faster than they can be cleared by the system, immune complex disease may occur. Examples of such disorders are drug sensitivity, **rheumatoid arthritis**, and a disease called **systemic lupus erythematosus**, or SLE.

The method generally used for detecting immune complexes is examination of a tissue obtained by biopsy (removal and examination of tissue sample) and the subsequent use of different staining techniques with specific antibodies. However, since tissue biopsies do not provide information about the level of complexes still in the circulatory system, serum assays obtained from blood samples that indirectly detect circulating immune complexes are useful. However, due to the variability of these complexes, several test methods may be used. Also, as most immune complex assays have not been standardized, more than one test may be required to achieve accurate results.

Preparation

This test requires a blood sample. It is not necessary for the patient to be in a **fasting** (nothing to eat or drink) state before the test.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Normally, immune complexes are not detected in the blood.

Abnormal results

The presence of detectable immune complexes in the blood is important in the diagnosis of autoimmune diseases, such as SLE and rheumatoid arthritis. However, for definitive diagnosis, the results of other studies must be considered with the presence of any immune complex. For example, immune complexes are associated with high numbers of a component called antinuclear antibodies in the diagnosis of systemic lupus erythematosus. A different example is the kidneys. Because of their filtering functions, elements in the kidneys called renal glomeruli can be affected by immune complexes. In such cases, renal biopsy is used to provide conclusive evidence for immune complex.

Immunodeficiency

Definition

Immunodeficiency disorders are a group of disorders in which part of the immune system is missing or defective. Therefore, the body's ability to fight infections is impaired. As a result, the person with an immunodeficiency disorder has frequent infections—thus, are at greater susceptibility to infection—that are generally more severe and last longer than usual. The infections involving immunodeficiency disorders commonly reside in the skin, throat, ears, sinuses, lungs, brain, spinal cord, urinary tract, and intestines.

Demographics

These disorders are caused by genetic or hereditary defects and, as such, can happen to anyone regardless of age or gender. While some immunodeficiency disorders are commonly scattered within the human population, other types are only infrequently found. Even though numerous types of such disorders exist they all have one feature in common: each involves a defect of a specific function of the body's overall immune system.

Description

The immune system is the body's main method for fighting infections. Any defect in the immune system decreases a person's ability to fight infections. A person with an immunodeficiency disorder may get more frequent infections, heal more slowly, and have a higher incidence of some cancers.

The normal immune system involves a complex interaction of certain types of cells that can recognize and attack "foreign" invaders (called antigens), such as bacteria, viruses, toxins, fungi, and blood or tissues from other humans or species. It also plays a role in fighting cancer. The immune system has both innate and adaptive components. Innate immunity is made up of immune protections people are born with. Adaptive immunity develops throughout life. It adapts to fight off specific invading organisms. Adaptive immunity is divided into two components: humoral immunity and cellular immunity.

The innate immune system is made up of the skin (which acts as a barrier to prevent organisms from entering the body), white blood cells called phagocytes, a system of proteins called the complement system, and chemicals called interferons. When phagocytes encounter an invading organism, they surround and engulf it to destroy it. The complement system also attacks bacteria. The elements in the complement system create a hole in the outer layer of the target cell, which leads to the death of the cell.

The adaptive component of the immune system is extremely complex, and is still not entirely understood. Basically, it has the ability to recognize an organism or tumor cell as not being a normal part of the body, and to develop a response to attempt to eliminate it.

The humoral response of adaptive immunity involves a type of cell called B lymphocytes. B lymphocytes manufacture proteins called antibodies (which are also called immunoglobulins). Antibodies attach themselves to the invading foreign substance. This allows the phagocytes to begin engulfing and destroying the organism. The action of antibodies also activates the complement system. The humoral response is particularly useful for attacking bacteria.

The cellular response of adaptive immunity is useful for attacking viruses, some parasites, and possibly cancer cells. The main type of cell in the cellular response is T lymphocytes. There are helper T lymphocytes and killer T lymphocytes. The helper T lymphocytes play a role in recognizing invading organisms, and they also help killer T lymphocytes to multiply. As the name suggests, killer T lymphocytes act to destroy the target organism.

Defects can occur in any component of the immune system or in more than one component (combined immunodeficiency). Different immunodeficiency diseases involve different components of the immune system. The defects can be inherited and/or present at birth (congenital) or acquired.

Congenital immunodeficiency disorders

Congenital (primary) immunodeficiency is present at the time of birth, and is the result of genetic defects. These immunodeficiency disorders are also called primary immunodeficiencies. The disorders are generally classified according to the part of the immune system that is improperly functioning. In research published in 2013, the World Health Organization (WHO) estimated that over 176 primary immunodeficiency disorders are

present around the world. These disorders are thought to be more common than previously thought, and significantly underdiagnosed. WHO suggested that data points to six million people worldwide living with such disorders. In the United States, the National Institute of Child Health and Human Development estimates about 400 children are born annually with a primary immunodeficiency disorder. It also states that roughly 25,000–50,000 people are living in any given year with such a disorder. The number of new cases is rising in the United Sates as new laboratory tests become more commonly available. Congenital immunodeficiencies may occur because of defects in B lymphocytes, T lymphocytes, or both. They also can occur in the innate immune system.

HUMORAL IMMUNITY DISORDERS. Bruton's agammaglobulinemia, also known as X–linked agammaglobulinemia, is a congenital immunodeficiency disorder. The defect results in a decrease or absence of B lymphocytes, and, therefore, a decreased ability to make antibodies. People with this disorder are particularly susceptible to infections of the throat, skin, middle ear, and lungs. It is seen only in males because it is caused by a genetic defect on the X chromosome. Since males have only one X chromosome, they always have the defect if the gene is present. Females can have the defective gene, but since they have two X chromosomes, there will be a normal gene on the other X chromosome to counter it. Women may pass the defective gene on to their male children.

B LYMPHOCYTE DEFICIENCES. If there is an abnormality in either the development or function of B lymphocytes, the ability to make antibodies will be impaired. This allows the body to be susceptible to recurrent infections.

A type of B lymphocyte deficiency involves a group of disorders called selective immunoglobulin deficiency syndomes. Immunoglobulin is another name for antibody, and there are five different types of immunoglobulins (called IgA, IgG, IgM, IgD, and IgE). The most common type of immunoglobulin deficiency is selective IgA deficiency, occurring in about one in every 500 white (Caucasian) persons. The amounts of the other antibody types are normal. Some patients with selective IgA deficiency experience no symptoms, while others have occasional lung infections and **diarrhea**. In another immunoglobulin disorder, IgG and IgA antibodies are deficient and there is increased IgM. People with this disorder tend to get severe bacterial infections.

Common variable immunodeficiency is another type of B lymphocyte deficiency. In this disorder, the production of one or more of the immunoglobulin types is decreased and the antibody response to infections is impaired. It generally develops around the age of 10 to 20 years. The symptoms vary among affected people. Most people with this disorder have frequent infections, and some of them also experience anemia and **rheumatoid arthritis**. Many people with common variable immunodeficiency develop cancer.

T LYMPHOCYTE DEFICIENCIES. Severe defects in the ability of T lymphocytes to mature results in impaired immune responses to infections with antigens, such as viruses, fungi, and certain types of bacteria. These infections are usually severe and can be fatal.

DiGeorge syndrome is a T lymphocyte deficiency that starts during fetal development and is the result of a deletion in a particular chromosome. Children with DiGeorge syndrome either do not have a thymus or have an underdeveloped thymus. Since the thymus is a major organ that directs the production of T–lymphocytes, these patients have very low numbers of T–lymphocytes. They are susceptible to recurrent infections, and usually have physical abnormalities as well. For example, they may have low–set ears, a small receding jawbone, and wide–spaced eyes. People with DiGeorge syndrome are particularly susceptible to viral and **fungal infections**.

In some cases, no treatment is required for DiGeorge syndrome because T lymphocyte production improves. Either an underdeveloped thymus begins to produce more T lymphocytes or organ sites other than the thymus compensate by producing more T lymphocytes.

COMBINED IMMUNODEFICIENCIES. Some types of immunodeficiency disorders affect both B lymphocytes and T lymphocytes. For example, **severe combined immunodeficiency** disease (SCID), sometimes commonly called Bubble Boy Syndrome, is caused by the defective development or function of these two types of lymphocytes. It results in impaired humoral and cellular immune responses. SCID usually is recognized during the first year of life. It tends to cause a fungal infection of the mouth (thrush), diarrhea, **failure to thrive**, and serious infections. If not treated with a bone marrow transplant, a person with SCID will generally die from infections before age two. It is reported that the prevalence of SCID is one in 100,000 births, although that figure is regularly considered an underestimate. In some local populations, this figure is much greater. For instance, in the Navajo population within the United States, it is reported that one in 2,000 babies inherit SCID.

DISORDERS OF INNATE IMMUNITY. Disorders of innate immunity affect phagocytes or the complement system. These disorders also result in recurrent infections.

WWW.BOOKBAZ.IR

Acquired immunodeficiency disorders

Acquired (secondary) immunodeficiency is more common than congenital immunodeficiency. It is frequently the result of an infectious process or other disease, **malnutrition**, medications/drugs, or **aging**. For example, the human immunodeficiency virus (HIV) is the virus that causes acquired immunodeficiency syndrome (**AIDS**). However, this is not the most common cause of acquired immunodeficiency.

Acquired immunodeficiency often occurs as a complication of other conditions and diseases. For example, the most common causes of acquired immunodeficiency are malnutrition, some types of cancer, and infections. People who weigh less than 70% of the average weight of persons of the same age and gender are considered to be malnourished. Examples of types of infections that can lead to immunodeficiency are **chickenpox**, cytomegalovirus, German **measles**, measles, **tuberculosis**, **infectious mononucleosis** (Epstein–Barr virus), chronic hepatitis, lupus, and bacterial and fungal infections.

In 2003, a new infection emerged that produces immunodeficiency. **Severe acute respiratory syndrome (SARS)** mysteriously appeared in a hospital in China. It eventually affected 8,000 people in Asia and Canada, killing 800 altogether. **Fever**, lower respiratory tract symptoms, and abnormal chest x rays characterize the disease. However, it also produces immunodeficiency. No cases of the disease were reported from July 2003 through December 2003, but scientists feared it would reappear. Thus, the World Health Organization (WHO) set up a network of medical and research professionals to deal with **SARS**. As of May 2006, the SARS infection had been completely contained. However, it is not considered eradicated, so could possibility return to infect the human population.

Sometimes, acquired immunodeficiency is brought on by drugs used to treat another condition. For example, patients who have an organ transplant are given drugs to suppress the immune system so the body will not reject the organ. Also, some **chemotherapy** drugs, which are given to treat cancer, have the side effect of killing cells of the immune system. During the period of time that these drugs are being taken, the risk of infection increases. It usually returns to normal after the person stops taking the drugs.

Causes and symptoms

Congenital immunodeficiency is caused by genetic defects that generally occur while the fetus is developing in the womb. These defects affect the development and/or function of one or more of the components of the immune system, such as lymphoid tissue within bone marrow, thymus, lymph nodes, tonsils, spleen, and gastrointestinal tract. Acquired immunodeficiency is the result of a disease process, and it occurs later in life. The causes can be diseases, infections, or the side effects of drugs given to treat other conditions.

People with an immunodeficiency disorder tend to become infected by organisms that do not usually cause disease in healthy persons. The major symptoms of most immunodeficiency disorders are repeated infections that heal slowly. These chronic infections cause symptoms that persist for long periods of time. People with chronic infection tend to be pale and thin. They may have skin **rashes**. Their lymph nodes tend to be larger than normal and their liver and spleen may be enlarged, too. The lymph nodes are small organs that house antibodies and lymphocytes. Broken blood vessels, especially near the surface of the skin, may be seen. This can result in black–and–blue marks in the skin. The person may lose hair from their head. Sometimes, a red inflammation of the lining of the eye (**conjunctivitis**) is present. They may have a crusty appearance in and on the nose from chronic nasal dripping.

Diagnosis

Usually, the first sign that a person might have an immunodeficiency disorder is that they do not improve rapidly when given **antibiotics** to treat an infection. Strong indicators that an immunodeficiency disorder may be present are when rare diseases occur or the patient gets ill from organisms that do not normally cause diseases, especially if the patient repeatedly is infected. If this happens in very young children, it is an indication that a genetic defect may be causing an immunodeficiency disorder. When this situation occurs in older children or young adults, their medical history will be reviewed to determine if childhood diseases may have caused an immunodeficiency disorder. Other possibilities will then be considered, such as recently acquired infections—for example, HIV, hepatitis, tuberculosis, etc.

Laboratory tests are used to determine the exact nature of the immunodeficiency. Most tests are performed on blood samples. Blood contains antibodies, lymphocytes, phagocytes, and complement components—all of the major immune components that might cause immunodeficiency. A blood cell count will determine if the number of phagocytic cells or lymphocytes is below normal. Lower than normal counts of either of these two cell types correlates with immunodeficiencies. The blood cells also are checked

for their appearance. Sometimes a person may have normal cell counts, but the cells are structurally defective. If the lymphocyte cell count is low, further testing is usually done to determine whether any particular type of lymphocyte is lower than normal. A lymphocyte proliferation test is done to determine if the lymphocytes can respond to stimuli. The failure to respond to stimulants correlates with immunodeficiency. A process called electrophoresis can measure antibody levels. Complement levels can be determined by immunodiagnostic tests.

Treatment

There is no cure for immunodeficiency disorders. Therapy is aimed at controlling infections and, for some disorders, replacing defective or absent components.

Patients with Bruton's agammaglobulinemia must be given periodic injections of a substance called **gamma globulin** throughout their lives to make up for their decreased ability to make antibodies. The gamma globulin preparation contains antibodies against common invading bacteria. If left untreated, the disease usually is fatal.

Common variable immunodeficiency also is treated with periodic injections of gamma globulin throughout life. Additionally, antibiotics are given when necessary to treat infections.

Patients with selective IgA deficiency usually do not require any treatment. Antibiotics can be given for frequent infections.

In some cases, treatment is not required for DiGeorge syndrome because T lymphocyte production improves on its own. Either an underdeveloped thymus begins to produce more T lymphocytes or organ sites other than the thymus compensate by producing more T lymphocytes. In some severe cases, a bone marrow transplant or thymus transplant can be done to correct the problem.

For patients with SCID, **bone marrow transplantation** is necessary. In this procedure, healthy bone marrow from a donor who has a similar type of tissue (usually a relative, such as a brother or sister) is removed. The bone marrow is a substance that resides in the cavity of bones. Such marrow produces blood including some of the white blood cells that make up the immune system. The bone marrow of the person receiving the transplant is destroyed, and is then replaced with marrow from the donor.

Treatment of the HIV infection that causes AIDS consists of drugs called antiretrovirals. These drugs attempt to inhibit the process that the virus goes through to kill T lymphocytes. Several of these drugs used in various combinations with one another can prolong the time period before the disease becomes apparent. However, this treatment is not a cure. Other treatments for people with AIDS are aimed at the particular infections and conditions that arise because of the impaired immune system. SARS is a relatively new acquired disease. Treatment to date involves combination therapy with **steroids** and interferon and supplemental oxygen for breathing difficulties. In 2004, the U.S. Food and Drug Administration approved the drug octagam 5% (Immune Globulin Intravenous [Human] 5%), an intravenous immunoglobulin product from the company Octapharma AG, to treat primary immunodeficiency diseases. At that time, the drug had been used in Europe for over ten years for the same purpose.

In most cases, immunodeficiency caused by malnutrition is reversible. The health of the immune system is directly linked to the nutritional status of the patient. Among the essential nutrients required by the immune system are proteins, **vitamins**, iron, and zinc.

For people being treated for cancer, periodic relief from chemotherapy drugs can restore the function of the immune system.

In general, people with immunodeficiency disorders should maintain a healthy diet because malnutrition can aggravate immunodeficiencies. They also should avoid being near people who have colds or are sick because they can easily acquire new infections. For the same reason, they should practice good personal hygiene, especially dental care. People with immunodeficiency disorders also should avoid eating undercooked food because it might contain bacteria that could cause infection. This food would not cause infection in persons with healthy immune systems, but in someone with an immunodeficiency, food is a potential source of infectious organisms. People with immunodeficiency should be given antibiotics at the first indication of an infection.

Prognosis

The prognosis depends on the type of immunodeficiency disorder. People with Bruton's agammaglobulinemia who are given injections of gamma globulin generally live into their 30s or 40s. They often die from chronic infections, usually of the lung. People with selective IgA deficiency generally live normal lives. They may experience problems if given a blood **transfusion**, and so they should wear a Medic Alert bracelet or have some other way of alerting any physician who treats them that they have this disorder.

WWW.BOOKBAZ.IR

KEY TERMS

Agammaglobulinemia—The lack of gamma globulins in the blood. Antibodies are the main gamma globulins of interest, so this term means a lack of antibodies.

SCID is the most serious of the immunodeficiency disorders. If a bone marrow transplant is not successfully performed, the child usually will not live beyond two years old.

People with HIV/AIDS are living longer than in the past because of **antiretroviral drugs** that became available in the mid-1990s. However, AIDS still is a fatal disease. People with AIDS usually die of opportunistic infections, which are infections that occur because the impaired immune system is unable to fight them.

Some complications that can occur include frequent or persistent illnesses and the increased risk from certain cancers. Infections are also much more likely with people having immunodeficiency disorders.

Prevention

There is no way to prevent a congenital immunodeficiency disorder. However, individuals with a congenital immunodeficiency disorder might want to consider **genetic counseling** before having children to find out if there is a chance they will pass the defect on to their children.

Some of the infections associated with acquired immunodeficiency can be prevented or treated before they cause problems. For example, there are effective treatments for tuberculosis and most bacterial and fungal infections. HIV infection can be prevented by practicing "safer sex" and not using illegal intravenous drugs. These are the primary routes of transmitting the virus. For people who do not know the HIV status of the person with whom they are having sex, safer sex involves using a condom.

Malnutrition can be prevented by getting adequate **nutrition**. Malnutrition tends to be more of a problem in developing countries.

Immunoelectrophoresis

Definition

Immunoelectrophoresis, also called **gamma globulin** electrophoresis, or immunoglobulin electrophoresis, is a method of determining the blood levels of three major immunoglobulins: immunoglobulin M (IgM), immunoglobulin G (IgG), and immunoglobulin A (IgA).

Purpose

Immunoelectrophoresis is a powerful analytical technique with high resolving power as it combines separation of antigens by electrophoresis with immunodiffusion against an antiserum. The increased resolution is of benefit in the immunological examination of serum proteins. Immunoelectrophoresis aids in the diagnosis and evaluation of the therapeutic response in many disease states affecting the immune system. It is usually requested when a different type of electrophoresis, called a serum **protein electrophoresis**, has indicated a rise at the immunoglobulin level. Immunoelectrophoresis is also used frequently to diagnose **multiple myeloma**, a disease affecting the bone marrow.

Precautions

Drugs that may cause increased immunoglobulin levels include therapeutic gamma globulin, hydralazine, isoniazid, phenytoin (Dilantin), procainamide, **oral contraceptives**, **methadone**, **steroids**, and **tetanus** toxoid and antitoxin. The laboratory should be notified if the patient has received any vaccinations or immunizations in the six months before the test. This is mainly because prior immunizations lead to the increased immunoglobulin levels resulting in false positive results.

Because immunoelectrophoresis is not quantitative, it is being replaced by a procedure called immunofixation, which is more sensitive and easier to interpret.

Description

Serum proteins separate in agar gels under the influence of an electric field into albumin, alpha 1, alpha 2, and beta and gamma globulins. Immunoelectrophoresis is performed by placing serum on a slide containing a gel designed specifically for the test. An electric current is then passed through the gel, and immunoglobulins, which contain an electric charge, migrate through the gel according to the difference in their individual electric charges. Antiserum is placed alongside the slide to identify the specific type of immunoglobulin present. The results are used to identify different disease entities, and to aid in monitoring the course of the disease and the therapeutic response of the patient to such conditions as immune deficiencies, autoimmune disease, chronic infections, chronic viral infections, and intrauterine fetal infections.

There are five classes of antibodies: IgM, IgG, IgA, IgE, and IgD.

IgM is produced upon initial exposure to an antigen. For example, when a person receives the first tetanus **vaccination**, antitetanus antibodies of the IgM class are produced 10–14 days later. IgM is abundant in the blood but is not normally present in organs or tissues. IgM is primarily responsible for ABO blood grouping and rheumatoid factor, yet is involved in the immunologic reaction to other infections, such as hepatitis. Since IgM does not cross the placenta, an elevation of this immunoglobulin in the newborn indicates intrauterine infection such as **rubella**, cytomegalovirus (CMV) or a sexually transmitted disease (STD).

IgG is the most prevalent type of antibody, comprising approximately 75% of the serum immunoglobulins. IgG is produced upon subsequent exposure to an antigen. As an example, after receiving a second tetanus shot, or booster, a person produces IgG antibodies in 5–7 days. IgG is present in both the blood and tissues, and is the only antibody to cross the placenta from the mother to the fetus. Maternal IgG protects the newborn for the first months of life, until the infant's immune system produces its own antibodies.

IgA constitutes approximately 15% of the immunoglobulins within the body. Although it is found to some degree in the blood, it is present primarily in the secretions of the respiratory and gastrointestinal tract, in saliva, colostrum (the yellowish fluid produced by the breasts during late **pregnancy** and the first few days after **childbirth**), and in tears. IgA plays an important role in defending the body against invasion of germs through the mucous membrane-lined organs.

IgE is the antibody that causes acute allergic reactions; it is measured to detect allergic conditions. IgD, which constitutes the smallest portion of the immunoglobulins, is rarely evaluated or detected, and its function is not well understood.

Preparation

This test requires a blood sample.

Aftercare

Because this test is ordered when either very low or very high levels of immunoglobulins are suspected, the patient should be alert for any signs of infection after the test, including **fever**, chills, rash, or skin **ulcers**. Any bone **pain** or tenderness should also be immediately reported to the physician.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or bruising.

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A protein manufactured by the white blood cells to neutralize an antigen in the body. In some cases, excessive formation of antibodies leads to illness, allergy, or autoimmune disorders.

Antigen—A substance that can cause an immune response, resulting in production of an antibody, as part of the body's defense against infection and disease. Many antigens are foreign proteins not found naturally in the body, and include germs, toxins, and tissues from another person used in organ transplantation.

Autoimmune disorder—A condition in which antibodies are formed against the body's own tissues; for example, in some forms of arthritis.

Results

Reference ranges vary from laboratory to laboratory and depend upon the method used. For adults, normal values are usually found within the following ranges (1 mg = approximately 0.000035 oz. and 1 dL = approximately 0.33 oz.):

- IgM: 60–290 mg/dL
- IgG: 700–1,800 mg/dL
- IgA: 70–440 mg/dL

Abnormal results

Increased IgM levels can indicate Waldenström's macroglobulinemia, a malignancy caused by secretion of IgM at high levels by malignant lymphoplasma cells. Increased IgM levels can also indicate chronic infections, such as hepatitis or mononucleosis and autoimmune diseases, like **rheumatoid arthritis**.

Decreased IgM levels can be indicative of **AIDS**, **immunosuppression** caused by certain drugs like steroids or dextran, or leukemia.

Increased levels of IgG can indicate chronic **liver disease**, autoimmune diseases, hyperimmunization reactions, or certain chronic infections, such as **tuberculosis** or **sarcoidosis**.

Decreased levels of IgG can indicate **Wiskott-Aldrich syndrome**, a genetic deficiency caused by inadequate synthesis of IgG and other immunoglobulins. Decreased IgG can also be seen with AIDS and leukemia.

Increased levels of IgA can indicate chronic liver disease, chronic infections, or inflammatory bowel disease.

Decreased levels of IgA can be found in ataxia, a condition affecting balance and gait, limb or eye movements, speech, and telangiectasia, an increase in the size and number of the small blood vessels in an area of skin, causing redness. Decreased IgA levels are also seen in conditions of low blood protein (hypoproteinemia), and drug immuno-suppression.

Immunoglobulin deficiency syndromes

Definition

Immunoglobulin deficiency syndromes are a group of **immunodeficiency** disorders in which the patient has a reduced number of or lack of antibodies.

Demographics

The disorders can appear in anyone, from newborn babies to the elderly.

Description

Immunoglobulins (Ig), also commonly known as antibodies, are **gamma globulin** proteins. That is, they are a type of protein found in the blood and other fluids of humans and other vertebrates. Immunoglobulins are used to neutralize bacteria, viruses, and other invading foreign substances. There are five major classes of antibodies: IgG, IgM, IgA, IgD, and IgE. Each differs in its functional location, physical properties, and ability to counter foreign substances within the body.

- IgG is the most abundant of the classes of immunoglobulins. It is the antibody for viruses, bacteria, and antitoxins. In addition, it is found in most tissues and plasma. It is also the only Ig that is able to help provide immunity to a mother's fetus.
- IgM is the first antibody present in an immune response.
- IgA is an early antibody for bacteria and viruses. It is found in saliva, tears, and all other mucous secretions such as within respiratory and urogenital tracts.
- IgD activity is not well understood. However, research has shown that it functions primarily as a receptor on B–cells that have yet to be subjected to antigens.
- IgE is present in respiratory secretions. It is an antibody for parasitic diseases (such as those caused by parasitic worms), Hodgkin's disease, hay fever, atopic dermatitis, and allergic asthma.

All antibodies are made by B–lymphocytes (B–cells). Any disease that harms the development or function of B–cells causes a decrease in the amount of antibodies produced. Since antibodies are essential in fighting infectious diseases, people with immunoglobulin deficiency syndromes become ill more often than those without the disorder. However, the cellular immune system is still functional, so these patients are more prone to infection caused by organisms usually controlled by antibodies. Most of these invading germs (microbes) make capsules, a mechanism used to confuse the immune system. In a healthy body, antibodies can bind to the capsule and overcome the bacteria's defenses. The bacteria that make capsules include the streptococci, meningococci, and *Haemophilus influenzae*. These organisms cause such diseases as otitis, **sinusitis**, **pneumonia**, **meningitis**, **osteomyelitis**, septic arthritis, and **sepsis**. Patients with immunoglobulin deficiencies are also prone to some viral infections, including echovirus, enterovirus, and **hepatitis B**. They may also have a bad reaction to the attenuated version of the **polio** virus vaccine.

There are two types of immunodeficiency diseases: secondary and primary. Secondary disorders occur in normally healthy bodies that have an underlying disease. Once the disease is treated, the immunodeficiency is reversed.

Primary immunodeficiency diseases occur because of defective B–cells or antibodies. They account for approximately 50% of all immunodeficiencies, and they are the most prevalent type of immunodeficiency disorders. These disorders include:

- X–linked agammaglobulinemia is an inherited disease. The defect is on the X chromosome and, consequently, this disease is seen more frequently in males than females. The defect results in a failure of B–cells to mature. Mature B–cells are capable of making antibodies and developing "memory," a feature in which the B–cell rapidly recognizes and responds to an infectious agent the next time it is encountered. Thus, patients with x–linked agammaglobulinemia do not generate mature B–cells. All classes of antibodies are decreased in agammaglobulinemia. It occurs in about one in 100,000 newborn males, without a predisposition to ethnic origin.
- Selective IgA deficiency, a mild but very common deficiency, is an inherited disease, resulting from a failure of B–cells to switch from making IgM, the early antibody, to IgA. Although the number of B–cells is normal, and the B–cells are otherwise normal (they can still make all other classes of antibodies), the amount of IgA produced is limited. This results in more infections of mucosal surfaces, such as the nose, mouth, throat, lungs, digestive tract, and intestines. Roughly no more than one in 333 people is inflicted by the deficiency; however, its frequency is dependent on various populations.
- Transient hypogammaglobulinemia of infancy is a temporary disease of unknown cause. Normally, it appears after birth of a child with increased infections but, sometimes, without any symptoms. It is believed to be caused by a defect in the development of T–helper cells (cells that recognize foreign antigens and activate T–and B–cells in an immune response). As the child ages, the number and condition of T–helper cells normally improves and this situation usually corrects itself. Hypogammaglobulinemia is characterized by low levels of gammaglobulin (antibodies) in the blood. During the disease period, patients have decreased levels of IgG antibodies, and sometimes of IgA and IgM antibodies. In laboratory tests, the antibodies that are present do not react well with infectious bacteria. The incidence of the disease varies widely in infants.
- Common variable immunodeficiency, which includes a group of primary immunodeficiencies, is a defect in both B cells and T–lymphocytes. The differences of its members are the result of the underlying causes. Most causes are unknown. However, all result in a near complete lack of antibodies in the blood, and all occur very frequently with respect to other such related diseases.
- Ig heavy chain deletions is a genetic disease in which part of the antibody molecule is not produced. It results in the loss of several antibody classes and subclasses, including most IgG antibodies and all IgA and IgE antibodies. The disease occurs because part of the gene for the heavy chain has been lost.

WWW.BOOKBAZ.IR

- Selective IgG subclass deficiencies is a group of genetic diseases in which some of the subclasses of IgG are not made. There are four subclasses in the IgG class of antibodies. As the B–cell matures, it can switch from one subclass to another. In these diseases there is a defect in the maturation of the B–cells that results in a lack of switching.
- IgG deficiency with hyper–IgM is a disease that results when the B–cell fails to switch from making IgM to IgG. This produces an increase in the amount of IgM antibodies present and a decrease in the amount of IgG antibodies. This disease is the result of a genetic mutation.
- Severe combined immunodeficiency (SCID) is not strictly a deficiency of immunoglobulin, although it is often categorized within this group. It occurs due to the absence or dysfunction of important immune cells called T–cells, or of both T–and B–cells. The condition can be X–linked, in which case more males than females are affected, or it can be inherited in an autosomal fashion (in which case males and females can be equally affected). In SCID, the thymus gland (which produces T–cells) may be abnormal.

Causes and symptoms

Immunoglobulin deficiencies are the result of congenital defects affecting the development and function of B lymphocytes (B–cells). There are two main points in the development of B–cells when defects can occur. First, B–cells can fail to develop into antibody–producing cells. X–linked agammaglobulinemia is an example of this disease. Secondly, B–cells can fail to make a particular type of antibody or fail to switch classes during maturation. Initially, when B–cells start making antibodies for the first time, they make IgM. As they mature and develop memory, they switch to one of the other four classes of antibodies. Failures in switching or failure to make a subclass of antibody leads to immunoglobulin deficiency diseases. Another mechanism that results in decreased antibody production is a defect in T–helper cells. Generally, defects in T–helper cells are listed as severe combined immunodeficiencies.

Symptoms are persistent and frequent infections, **diarrhea**, **failure to thrive**, and malabsorption (of nutrients).

Diagnosis

An immunodeficiency disease is suspected when children become ill frequently, especially from the same organisms, or from organisms that do not usually cause infection. Standard treatments may also fail. The profile of organisms that cause infection in patients with immunoglobulin deficiency syndrome is unique and is preliminary evidence for this disease. Laboratory tests are performed to verify the diagnosis. Antibodies can be found in the blood. Blood is collected and analyzed for the content and types of antibodies present. Depending on the type of immunoglobulin deficiency, the laboratory tests will show a decrease or absence of antibodies or specific antibody subclasses.

KEY TERMS

Antibody—Another term for immunoglobulin. A protein molecule that specifically recognizes and attaches to infectious agents.

T–helper cell—A type of cell that recognizes foreign antigens and activates T–and B–cells in an immune response.

Treatment

Immunodeficiency diseases cannot be cured. Intravenous administration of immunoglobulin may temporarily boost immunity, but these treatments may need to be repeated at regular intervals. Acute or chronic bacterial infections are treated with **antibiotics**; antifungal drugs are also available. Very few drugs are effective against viral diseases. In severe cases, **bone marrow transplantation** may be considered and can cure some cases of immunodeficiency

Bone marrow transplantation can, in most cases, completely correct the immunodefiency.

Prognosis

Patients with immunoglobulin deficiency syndromes must practice impeccable health maintenance and care, paying particular attention to optimal dental care, in order to stay in good health.

Prevention

There is not a known way to prevent immunoglobulin deficiency syndromes.

Immunologic therapies

Definition

Immunologic therapy is an approach to the treatment of disease by using medicine to stimulate the body's natural immune response.

Purpose

Immunologic therapy is used to improve the immune system's natural ability to fight such diseases as cancer, hepatitis, and **AIDS**. These drugs may also be used to help the body recover from **immunosuppression** resulting from such treatments as **chemotherapy** or **radiation therapy**.

Description

Most drugs in this category are synthetic versions of substances produced naturally in the body. In their natural forms, these substances help defend the body against disease. There are several different types of drugs available:

- Aldesleukin (Proleukin) is an artificial form of interleukin-2, which helps white blood cells work. Aldesleukin is administered to patients with kidney cancers and skin cancers that have spread to other parts of the body.
- Filgrastim (Neupogen) and sargramostim (Leukine) are versions of natural substances called colony-stimulating factors, which encourage the bone marrow to make new white blood cells.
- Epoetin (Epogen, Procrit) is a synthetic version of human erythropoietin, which stimulates the bone marrow to make new red blood cells.
- Thrombopoietin stimulates the production of platelets, which are disk-shaped bodies in the blood that are important in clotting.
- Interferons are substances that the body produces naturally, using cells in the immune system to fight infections and tumors. Synthetic interferons carry such brand names as Alferon, Roferon, or Intron A. Some of the interferons that are currently in use as medications are recombinant interferon alfa-2a, recombinant interferon alfa-2b, interferon alfa-n1, and interferon alfa-n3. Alfa interferons are used to treat hairy cell leukemia, malignant melanoma, and Kaposi's sarcoma, which is a type of cancer associated with HIV infection. Interferons are also used to treat conditions such as laryngeal papillomatosis, genital warts, and certain types of hepatitis.

Recommended dosage

The recommended dosage depends on the type of immunologic therapy. For some medicines, the physician will decide the dosage for each patient, taking into account a patient's weight and use of other medications. Some drugs used in immunologic therapy are given only in a hospital under a physician's supervision. Patients who are taking drugs that can be used at home should consult the prescribing physician or their pharmacist for the correct dosage.

Most of these drugs come in an injectable form, which is generally administered by a cancer care provider.

WWW.BOOKBAZ.IR

Precautions

Aldesleukin

This drug may temporarily increase the patient's risk of getting infections. It may also lower the number of platelets in the blood, interfering with the blood's ability to clot. Taking the following precautions may reduce the chance of such complications:

- Avoid people with infectious diseases whenever possible.
- Be alert to such signs of infection as fever, chills, sore throat, pain in the lower back or side, cough, hoarseness, or painful or difficult urination. If any of these symptoms occur, call a physician immediately.
- Be alert to such signs of bleeding problems as black or tarry stools, tiny red spots on the skin, blood in the urine or stools, or any other unusual bleeding or bruising.
- Take care to avoid cuts or other injuries, particularly when using knives, razors, nail clippers, and other sharp objects. The patient should consult his or her dentist for the best ways to clean the teeth and mouth without injuring the gums. In addition, patients should not have any dental work done without checking with their primary physician.
- Wash hands frequently, and avoid touching the eyes or inside of the nose unless the hands have just been washed.

Aldesleukin may make some disorders worse, including **chickenpox**, **shingles** (herpes zoster), **liver disease**, lung disease, **heart disease**, underactive thyroid, **psoriasis**, immune system problems, and mental problems. The medicine may also increase the risk of seizures (convulsions) in people with **epilepsy** or other seizure disorders. In addition, the drug's effects may be intensified in people with **kidney disease**, because their kidneys are slow to clear the medicine from their bodies.

Colony-stimulating factors

Certain drugs used in treating cancer reduce the body's ability to fight infections. Although colony-stimulating factors help restore the body's natural defenses, the process takes time. Getting prompt treatment for infections is important, even while the patient is taking these medications. Patients taking colony-stimulating factors should call their physician at the first sign of illness or infection, including a **sore throat**, **fever**, or chills.

People with certain medical conditions may have problems if they take colony-stimulating factors. Patients with kidney disease, liver disease, or conditions related to inflammation or immune system disorders may find that colony-stimulating factors make their disorder worse. People with heart disease may be more likely to experience such side effects as water retention and irregular heart rhythm while taking these drugs. Patients with lung disease may increase their risk of **shortness of breath**. People with any of these medical conditions should consult their personal physician before using colony-stimulating factors.

Epoetin

Epoetin may cause seizures (convulsions), especially in people with epilepsy or other seizure disorders. People taking epoetin should not drive, operate heavy machinery, or do anything else that would be dangerous to themselves or others in the event of a seizure.

Epoetin helps the body make new red blood cells, but it is not effective unless there are adequate stores of iron in the body. The patient's physician may recommend taking iron supplements or certain **vitamins** that help to maintain the body's iron supply. It is necessary to follow the physician's advice in this instance, as with any dietary supplements that should come only from a physician.

Epoetin given to laboratory animals during **pregnancy** caused **birth defects** in the tested species, including damage to the bones and spine. The drug, however, has not been reported to cause problems in human babies whose mothers took it during pregnancy. Nevertheless, women who are or may become pregnant should check with their physicians for the most up-to-date information on the safety of taking this medicine during pregnancy.

People with certain medical conditions may have problems if they take epoetin. For example, there appears to be a greater risk of side effects in people with high blood pressure, disorders of the heart or blood vessels, or a history of **blood clots**. In addition, epoetin may not work properly in people who have bone disorders or sickle cell anemia.

Interferons

Interferons may intensify the effects of alcohol and other drugs that slow down the central nervous system, including **antihistamines**, over-the-counter cold medicines, allergy medications, sleep aids, anticonvulsants, tranquilizers, some **pain** relievers, and **muscle relaxants**. Interferons may also intensify the effects of anesthetics, including the local anesthetics used for dental procedures. Patients taking interferons should consult their physicians before taking any of these medications.

Some people experience **dizziness**, unusual **fatigue**, or drowsiness while taking these drugs. Because of these possible problems, anyone taking these drugs should not drive, use heavy machinery, or do anything else that requires full alertness until they have determined how the drugs affect them.

Interferons often cause flu-like symptoms, including fever and chills. The prescribing physician may recommend taking **acetaminophen** (Tylenol) before—and sometimes after—each dose to keep the fever from getting too high. If the physician recommends taking acetaminophen, the patient should follow his or her instructions carefully.

Like aldesleukin, interferons may temporarily increase the risk of getting infections and lower the number of platelets in the blood, which may lead to clotting problems. Patients should observe these precautions for reducing the risk of infection and bleeding for aldesleukin.

People who have certain medical conditions may have problems if they take interferons. For example, the drugs may worsen some medical conditions, including heart disease, kidney disease, liver disease, lung disease, diabetes, bleeding problems, and certain psychiatric disorders. In people who have overactive immune systems, these drugs can even increase the activity of the immune system. People who have shingles or chickenpox, or who have recently been exposed to chickenpox, may increase their risk of developing severe problems in other parts of the body if they take interferons. People with a history of seizures or associated mental disorders may be at risk if they take interferon.

Elderly people appear to be at an increased risk of side effects from taking interferons.

Interferons may cause changes in the menstrual cycles of teenagers. Young women should discuss this possibility with their physicians. These drugs are not known to cause fetal death, birth defects, or other problems in humans when taken during pregnancy. Women who are pregnant or who may become pregnant should ask their physicians for the latest information on the safety of taking these drugs during pregnancy.

Women who are breastfeeding their babies may need to stop while taking this medicine. It is not yet known whether interferons pass into breast milk; however, because of the chance of serious side effects that might affect the baby, women should not breastfeed while taking interferon. Patients should consult their physician for more specific advice.

General precautions

Regular appointments with the doctor are necessary during immunologic therapy treatment. These checkups give the physician a chance to make sure the medicine is working and to monitor the patient for unwanted side effects.

Anyone who has had unusual reactions to the drugs used in immunologic therapy should inform the doctor before resuming the drugs. Any **allergies** to foods, dyes, preservatives, or other substances should also be reported.

Side effects

Aldesleukin

Aldesleukin may cause serious side effects. It is ordinarily given only in a hospital, where medical professionals can watch for early signs of problems. Medical tests may be performed to check for unwanted side effects. In general, anyone who has breathing problems, fever, or chills while being given aldesleukin should consult their doctor at once.

Other side effects should be brought to a physician's attention as soon as possible:

- dizziness
- drowsiness
- confusion
- agitation
- depression
- nausea and vomiting
- diarrhea
- sores in the mouth and on the lips
- tingling of hands or feet
- decrease in urination
- unexplained weight gain of 5 lb. (2 kg) or more

Some side effects of aldesleukin are usually temporary and do not need medical attention unless they are bothersome. These include dry skin, itchy or burning rash or redness followed by peeling, loss of appetite, and a general feeling of illness or discomfort.

Colony-stimulating factors

Patients sometimes experience mild pain in the lower back or hips in the first few days of treatment with colony-stimulating factors. This side effect is not a cause for concern and usually goes away within a few days. If the pain is intense or causes discomfort, the physician may prescribe a painkiller.

Other possible side effects include **headache**, joint or muscle pain, and skin rash or **itching**. These side

WWW.BOOKBAZ.IR

effects tend to disappear as the body adjusts to the medicine, and do not need medical treatment. If they continue, or if they interfere with normal activities, the patient should consult their physician.

Epoetin

Epoetin may cause such flu-like symptoms as muscle aches, bone pain, fever, chills, shivering, and sweating within a few hours after it is taken. These symptoms usually go away within 12 hours. If they persist or are severe, the patient should call their doctor. Other possible side effects of epoetin that do not need medical attention are **diarrhea**, nausea or **vomiting**, and fatigue or weakness.

Side effects that should be brought to a physician's attention as soon as possible include headache; vision problems; a rise in blood pressure; fast heartbeat; weight gain; or swelling of the face, fingers, lower legs, ankles, or feet. Anyone who has chest pain or seizures after taking epoetin should seek professional emergency medical attention immediately.

Interferons

Interferons may cause temporary hair loss (**alopecia**). Although this side effect may be upsetting because it affects the patient's appearance, it is not a sign that something is seriously wrong. The hair should grow back normally after treatment ends.

As the body adjusts to these medications, the patient may experience other side effects that usually go away during treatment. These include flu-like symptoms, alterations in the sense of taste, loss of appetite (anorexia), **nausea and vomiting**, skin **rashes**, and unusual fatigue. The patient should consult a doctor if these problems persist or if they interfere with normal life.

Other side effects are more serious and should be brought to a physician's attention as soon as possible:

- confusion
- difficulty thinking or concentrating
- nervousness
- depression
- sleep problems
- numbness or tingling in the fingers, toes, and face

General side effects

Other side effects are possible with any type of immunologic therapy. Anyone who has unusual symptoms during or after treatment with these drugs should contact the physician immediately.

KEY TERMS

Bone marrow—Soft tissue that fills the hollow centers of bones. Blood cells and platelets (disk-shaped bodies in the blood that are important in clotting) are produced in the bone marrow.

Chemotherapy—Treatment of an illness with chemical agents. The term is usually used to describe the treatment of cancer with drugs.

Hepatitis—Inflammation of the liver caused by a virus, chemical, or drug.

Immune response—The body's natural protective reaction against disease and infection.

Immune system—The system that protects the body against disease and infection through immune responses.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Seizure—A sudden attack, spasm, or convulsion.

Shingles—A disease caused by the Herpes zoster virus—the same virus that causes chickenpox. Symptoms of shingles include pain and blisters along one nerve, usually on the face, chest, stomach, or back.

Sickle cell anemia—An inherited disorder in which red blood cells contain an abnormal form of hemoglobin, a protein that carries oxygen.

Interactions

Anyone who has immunologic therapy should give their physician a list of all other medications that they take, including over-the-counter and herbal preparations. Some combinations of drugs may increase or decrease the effects of one or both drugs, or increase the likelihood of side effects.

Alternatives

Immunoprevention

Immunoprevention is a form of treatment that has been proposed as a form of cancer therapy. There are two types of immunoprevention: active and passive. Treatment that involves such immune molecules as cytokines, which are prepared synthetically, or other immune molecules that are not produced by patients themselves are called passive immunotherapy. By contrast, vaccines are a form of active immune therapy because they elicit an immune response from the patient's body. **Cancer vaccines** may be made of

whole tumor cells or from substances or fragments from the tumor known as antigens.

Adoptive immunotherapy

Adoptive immunotherapy involves stimulating T lymphocytes by exposing them to tumor antigens. These modified cells are grown in the laboratory and then injected into patients. Since the cells taken from a different person for this purpose are often rejected, patients serve both as donor and recipient of their own T cells. Adoptive immunotherapy is particularly effective in patients who have received massive doses of radiation and chemotherapy. In such patients, therapy results in immunosuppression (weakened immune systems), making them vulnerable to viral infections. For example, CMV-specific T cells can reduce the risk of cytomegalovirus (CMV) infection in organ transplant patients.

Immunosuppressant drugs

Definition

Immunosuppressant drugs, also called antirejection drugs, are used to inhibit or prevent the activity of the body's immune system. They have three major uses: to prevent the body from rejecting a transplanted organ; to treat such autoimmune diseases as **rheumatoid arthritis** (RA), Crohn's disease, ulcerative **colitis**, and **systemic lupus erythematosus** (SLE); and to treat a few inflammatory diseases that are not **autoimmune disorders**, such as long-term allergic **asthma**.

Purpose

When an organ—such as a liver, heart, or kidney—is transplanted from one person (the donor) into another (the recipient), the immune system of the recipient triggers the same response against the new organ that it would have against any foreign material, setting off a chain of events that can damage the transplanted organ. This process is called rejection. It can occur rapidly (acute rejection) or over a long period of time (chronic rejection). Rejection can occur despite close matching of the donated organ and the transplant patient. Immunosuppressant drugs greatly decrease the risks of rejection, protecting the new organ and preserving its function. These drugs act by blocking the recipient's immune system so that it is less likely to react against the transplanted organ. A wide variety of drugs are available to achieve this aim but work in different ways to reduce the risk of rejection.

In addition to being used to prevent organ rejection, immunosuppressant drugs are also used to treat severe skin disorders such as **psoriasis** and other

WWW.BOOKBAZ.IR

diseases such as rheumatoid arthritis, Crohn's disease (chronic inflammation of the digestive tract), and patchy hair loss (**alopecia** areata). These conditions are termed autoimmune diseases, indicating that the immune system is reacting against the body itself.

Description

Immunosuppressant drugs can be classified according to their specific molecular mode of action. There are four main categories of immunosuppressant drugs currently used in treating patients with transplanted organs:

- Cyclosporine (Neoral, Sandimmune, SangCya) acts by inhibiting T-cell activation, thus preventing T-cells from attacking the transplanted organ.
- Azathioprine (Imuran) disrupts the synthesis of DNA and RNA as well as the process of cell division.
- Monoclonal antibodies, including basiliximab (Simulect), daclizumab (Zenapax), and muromonab-CD3 (Orthoclone OKT3), act by inhibiting the binding of interleukin-2, which in turn slows down the production of T-cells in the patient's immune system.
- Corticosteroids such as prednisone (Deltasone, Orasone) suppress the inflammation associated with transplant rejection.

Immunosuppressant drugs can also be classified according to the specific organ that is transplanted:

- Basiliximab (Simulect) is used in combination with such other drugs as cyclosporine and corticosteroids in kidney transplants.
- Daclizumab (Zenapax) is used in combination with such other drugs as cyclosporine and corticosteroids in kidney transplants.
- Muromonab-CD3 (Orthoclone OKT3) is used along with cyclosporine in kidney, liver, and heart transplants.
- Tacrolimus (Prograf) is used in heart, liver, and kidney transplants. It is under study for bone marrow, pancreas, pancreatic island cell, and small bowel transplantation.
- Sirolimus (Rapamune, Rapamycin) is used in kidney transplants.

Most patients are prescribed a combination of drugs—sometimes called a multiple-drug cocktail—after their transplant, one from each of the main groups; for example, they may be given a combination of cyclosporine, azathioprine, and prednisone. Over a period of time, the doses of each drug and the number of drugs taken may be reduced as the risk of rejection decreases. Most transplant patients, however, will need to take at least one immunosuppressive medication for the rest of their lives.

The major limitation of immunosuppressant drugs is that they cannot target only those cells involved in graft or transplant rejection; immunosuppressants impair the immune responses of other cells, as well.

Other conditions

Some immunosuppressants treat a variety of autoimmune diseases:

- Azathioprine (Imuran) is used not only to prevent organ rejection in kidney transplants, but also in the treatment of rheumatoid arthritis. It has been used to treat chronic ulcerative colitis, although it has proved to be of limited value for this use.
- Cyclosporine (Sandimmune, Neoral) is used in heart, liver, kidney, pancreas, bone marrow, and heart/lung transplantation. The Neoral form of cyclosporine has been used to treat psoriasis and rheumatoid arthritis. The drug has also been used to treat many other conditions, including multiple sclerosis, diabetes, and myasthenia gravis.
- Glatiramer acetate (Copaxone) is used in the treatment of relapsing-remitting multiple sclerosis. In one study, glatiramer reduced the frequency of multiple sclerosis attacks by 75% over a two-year period.
- Mycophenolate (CellCept) is used along with cyclosporine in kidney, liver, and heart transplants. It has also been used to prevent the kidney problems associated with lupus erythematosus.
- Sirolimus (Rapamune, Rapamycin) is used in combination with other drugs, including cyclosporine and corticosteroids, in kidney transplants. The drug is also used to treat patients with psoriasis.

Recommended dosage

Immunosuppressant drugs are available only with a physician's prescription. They come in tablet, capsule, liquid, and injectable forms. The recommended dosage depends on the type and form of immunosuppressant drug and the purpose for which it is being used. Doses may be different for different patients. The prescribing physician or the pharmacist who filled the prescription will advise the patient on the correct dosages.

Patients who are taking immunosuppressant drugs should take them exactly as directed. They should never take smaller, larger, or more frequent doses of these medications. In addition, immunosuppressant drugs should never be taken for a longer

period of time than directed. The physician will decide exactly how much of the medicine each patient needs. Blood tests are usually necessary to monitor the action of these drugs.

Patients should always consult the prescribing physician before they stop taking an immunosuppressant drug.

Precautions

Patients who are taking immunosuppressant drugs should see their doctor on a regular basis. Periodic checkups will allow the physician to make sure the drug is working as it should and to monitor the patient for unwanted side effects. These drugs are very powerful and can cause serious side effects, including high blood pressure, kidney problems, and liver disorders. Some side effects may not show up until years after the medicine was used. Anyone who has been advised to take immunosuppressant drugs should thoroughly discuss the risks and benefits of these medications with the prescribing physician.

Immunosuppressant drugs lower a person's resistance to infection and can make infections harder to treat. The drugs can also increase the chance of uncontrolled bleeding. Anyone who has a serious infection or injury while taking immunosuppressant drugs should receive prompt medical attention and should make sure that the treating physician knows that he or she is taking an immunosuppressant medication. The prescribing physician should be immediately informed if signs of infection are present, such as **fever** or chills, **cough** or hoarseness, **pain** in the lower back or side, painful or difficult urination, bruising or bleeding, blood in the urine, or bloody or black, tarry stools. Other ways of preventing infection and injury include washing the hands frequently, avoiding sports in which injuries may occur, and being careful when using knives, razors, fingernail clippers, or other sharp objects. Avoiding contact with people who have infections is also important.

In addition, people who are taking or have been taking immunosuppressant drugs should not receive immunizations without consulting their physician. Because their resistance to infection has been lowered, people taking these drugs might get the disease that the vaccine is designed to prevent. People taking immunosuppressant drugs should avoid contact with anyone who has had a recent dose of oral **polio** vaccine, as there is a chance that the virus used to make the vaccine could be passed on to them.

Immunosuppressant drugs may cause the gums to become tender and swollen or to bleed. If this happens, a physician or dentist should be notified. Regular brushing, flossing, cleaning, and gum massage may help prevent this problem. A dentist can provide advice on how to clean the teeth and mouth without causing injury.

Special conditions

People who have certain diseases or disorders, or who are taking certain other medicines may have problems if they take immunosuppressant drugs. Before taking these drugs, patients should inform the prescribing physician about any other existing conditions.

ALLERGIES. Anyone who has had unusual reactions to immunosuppressant drugs in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Azathioprine has been considered a cause of **birth defects**. The British National Formulary, however, states: "Transplant patients immunosuppressed with azathioprine should not discontinue it on becoming pregnant; there is no evidence that azathioprine is teratogenic. There is less experience of cyclosporine in **pregnancy** but it does not appear to be any more harmful than azathioprine. The use of these drugs during pregnancy needs to be supervised in specialist units. Any risk to the offspring of azathioprine-treated men is small." Nonetheless, patients who are taking any immunosuppressive drug should consult with their physician before conceiving a child, and they should notify the doctor at once when there is any indication of pregnancy.

Basiliximab should not be used during pregnancy. The manufacturer recommends using adequate **contraception** during use of this drug, and for eight weeks following the final dose.

The manufacturers of tacrolimus and mycophenolate warn against their use during pregnancy, on the basis of findings from animal studies. They recommend using adequate contraception while taking these drugs, and for six weeks after the last dose.

The safety of **corticosteroids** during pregnancy has not been absolutely determined. There is some evidence that the use of these drugs during pregnancy may affect the baby's growth; however, this result is not certain and may vary with the medication used. Patients taking any steroid drug should consult with their physician before starting a family, and should notify their doctor at once if they think they are pregnant.

Most of these medicines have not been studied in humans during pregnancy. Women who are pregnant

WWW.BOOKBAZ.IR

or who may become pregnant and who need to take immunosuppressants should consult their physicians.

LACTATION. Immunosuppressant drugs pass into breast milk and may cause problems in nursing babies whose mothers take it. Breastfeeding is not recommended for women taking immunosuppressants.

OTHER MEDICAL CONDITIONS. People with any of the following conditions may have problems if they take immunosuppressant drugs:

- People who have shingles (herpes zoster) or chickenpox, or who have recently been exposed to chickenpox, may develop severe disease in other parts of their bodies when they take these medicines.
- Immunosuppressants may produce more intense side effects in people with kidney disease or liver disease, because their bodies are slow to get rid of the medicine.
- Oral forms of immunosuppressants may be less effective in people with intestinal problems, because the medicine cannot be absorbed into the body.

Before using immunosuppressants, people with these or other medical problems should make sure their prescribing physician is aware of their conditions.

Side effects

Increased risk of infection is a common side effect of all immunosuppressant drugs. The immune system protects the body from infections; when the immune system is suppressed, infections are more likely. Taking **antibiotics** such as co-trimoxazole (SXT, TMP-SMX, or TMP-sulfa) prevents some of these infections. Immunosuppressant drugs are also associated with a slightly increased risk of cancer, because the immune system plays a role in protecting the body against some forms of cancer. For example, the long-term use of immunosuppressant drugs carries an increased risk of developing **skin cancer** as a result of the combination of the drugs and exposure to sunlight.

Other side effects of immunosuppressant drugs are minor and usually go away as the body adjusts to the medicine. These include loss of appetite, nausea or **vomiting**, increased hair growth, and trembling or shaking of the hands. Medical attention is not necessary unless these side effects continue or cause problems.

The treating physician should be notified immediately if any of the following side effects occur:

- unusual tiredness or weakness
- fever or chills
- frequent need to urinate

Interactions

Immunosuppressant drugs may interact with other medicines. When interactions occur, the effects of one or both drugs may change or the risk of side effects may be greater. Other drugs may also have adverse effects on immunosuppressant therapy. It is particularly important for patients taking cyclosporine or tacrolimus to be careful about the possibility of **drug interactions**. Other examples of problematic interactions include:

- The effects of azathioprine may be greater in people who take allopurinol, a medicine used to treat gout.
- A number of drugs, including female hormones (estrogens), male hormones (androgens), the antifungal drug ketoconazole (Nizoral), the ulcer drug cimetidine (Tagamet), and the erythromycins (used to treat infections), may intensify the effects of cyclosporine. Certain herbs are also reported to interact with cyclosporine.
- When sirolimus is taken at the same time as cyclosporine, the blood levels of sirolimus may be increased to a level that produces severe side effects. Although these two drugs are usually used together, the dose of sirolimus should be taken four hours after the dose of cyclosporine.
- Tacrolimus is eliminated through the kidneys. When this drug is used with other medications that may harm the kidneys, such as cyclosporine, the antibiotics gentamicin and amikacin, or the antifungal drug amphotericin B, the blood levels of tacrolimus may rise. Careful kidney monitoring is essential when tacrolimus is given with any drug that might cause kidney damage. Tacrolimus is reported to interact with some over-the-counter herbal preparations.
- The risk of cancer or infection may be greater when immunosuppressant drugs are combined with certain other drugs that also lower the body's ability to fight disease and infection. These drugs include corticosteroids, especially prednisone; the anticancer drugs chlorambucil (Leukeran), cyclophosphamide (Cytoxan), and mercaptopurine (Purinethol); and the monoclonal antibody muromonab-CD3 (Orthoclone), which is used to prevent transplanted organ rejection.

Not every drug that may interact with immunosuppressant drugs is listed here. Anyone who takes immunosuppressant drugs should give their doctor a list of all other medicines—including **vitamins** and supplements—that he or she is taking and should ask whether there are any potential interactions that might interfere with treatment.

KEY TERMS

Antibody—A protein produced by the immune system in response to the presence in the body of an antigen.

Antigen—Any substance or organism that is foreign to the body. Examples of antigens include bacteria, bacterial toxins, viruses, or other cells or proteins.

Autoimmune disease—A disease in which the immune system is overactive and produces antibodies that attack the body's own tissues.

Corticosteroids—A class of drugs that are synthetic versions of the cortisone produced by the body. They rank among the most powerful anti-inflammatory agents.

Cortisone—A glucocorticoid compound produced by the adrenal cortex in response to stress. Cortisone is a steroid with anti-inflammatory and immunosuppressive properties.

Immune system—The network of organs, cells, and molecules that work together to defend the body from such foreign substances and organisms causing infection and disease as bacteria, viruses, fungi, and parasites.

Inflammation—A process occurring in body tissues, characterized by increased circulation and the accumulation of white blood cells. Inflammation also occurs in such disorders as arthritis and causes harmful effects.

Lymphocyte—A type of white blood cell involved in the immune response. The two main groups of lymphocytes are the B cells, which carry antibody molecules on their surface; and T cells, which destroy antigens.

Psoriasis—A skin disease characterized by itchy, scaly, red patches on the skin.

T cells—Any of several lymphocytes that have specific antigen receptors, and are involved in cell-mediated immunity and the destruction of antigen-bearing cells.

REVISED BY SAMUEL URETSKY, PHARMD
REVISED BY REBECCA FREY, PHD

Immunosuppression

Definition

Immunosuppression is the act of reducing or restraining the efficacy or activity level of the immune system. Immunosuppression may occur naturally or unintentionally, as in such conditions as **malnutrition**, cancer, **aging**, or **AIDS**; this category of immunosuppression is also known as nondeliberate immunosuppression. Nondeliberate immunosuppression may also come about as a side effect of **chemotherapy** treatment, **radiation therapy**, and other medications.

Deliberate immunosuppression is the use of drugs, surgery, radiotherapy, or other methods to suppress the immune system for a number of reasons, including to prevent organ rejection or the development of graft-versus-host disease after an organ, stem cell, or bone marrow transplant; to treat **autoimmune disorders**; and to prevent the development of hemolytic disease of the newborn, a fetal autoimmune disorder. Persons whose immune systems have been weakened by unintentional immunosuppression or who are undergoing deliberate immunosuppression are referred to as being immunocompromised.

Purpose

Deliberate immunosuppression has three main purposes:

- prevention of transplant rejection
- treatment of autoimmune disorders
- treatment of some nonautoimmune inflammatory diseases, such as long-term asthma

Description

Origins

Immunosuppression is a development of twentieth-century and early twenty-first-century medicine. Prior to the 1930s, no one attempted organ transplants, and there were no effective drugs to treat autoimmune disorders. In 1933, a team of surgeons attempted to transplant a kidney from a cadaver into a living patient, but as little was known about transplant rejection, the operation was a failure. Whole-body radiation therapy was then tried to lower the risk of organ rejection, but the patients died from its side effects. A class of **steroids** known as glucocorticoids (cortisone, prednisone, and similar drugs), which were first developed in the late 1940s and 1950s, proved to be useful in treating autoimmune disorders, but they did not improve the success rate of organ transplants when used by themselves.

It was not until the development of such drugs as 6-mercaptopurine (Purethinol) and azathioprine (Imuran) in the late 1950s that immunosuppressive drug therapy became the mainstay of treatment to prevent transplant rejection and relieve the symptoms of autoimmune disorders. The first patients who received successful organ transplants, in 1962 and 1964, were treated with a combination of steroid medications and azathioprine.

A number of different types of immunosuppressive drugs were developed in the late 1960s and in subsequent years, including methotrexate (Trexall), cyclosporine (Sandimmune), macrolide drugs like tacrolimus (Prograf) and sirolimus (rapamycin), and mycophenolate mofetil (MMF or CellCept), a less toxic alternative to azathioprine. In most cases, the effectiveness of these agents in immunosuppression was discovered before their mechanisms of action were understood. The advent of these newer drugs allowed for the introduction of combination immunosuppressive therapy, which has become the standard in both prevention and treatment of transplant rejection and the treatment of autoimmune disorders. Combination therapy is highly individualized in terms of the dosage levels as well as the specific drugs prescribed for each patient—a patient may be given different doses and combinations of drugs at different times.

Leukocytes and lymphocytes

An overview of the types and roles of white blood cells (also known as leukocytes or WBCs) in the immune system may be helpful in understanding how immunosuppression works. There are seven main types of WBCs. One group consists of the lymphocytes, which account for about 30% of all WBCs in the human body. There are three major types of lymphocytes, one belonging to the so-called innate immune system and the other two to the adaptive immune system. "Natural killer" (NK) cells, also known as large lymphocytes because of their size, belong to the innate immune system. They target tumor cells and cells infected by viruses. The other two types of

lymphocytes, also called small lymphocytes, are the T cells and B cells. T cells mature in the thymus gland, and B cells in the bone marrow. B cells produce antibodies, which are proteins that target specific antigens and foreign substances or organisms. T cells can be subdivided into helper T cells, which assist other WBCs in the immune system; cytotoxic T cells, which are implicated in transplant rejection; regulatory T cells, which help to protect against autoimmune disease; and memory T cells, which enable the immune system to "remember" past infections. Both B and T cells belong to the adaptive immune system.

Types of immunosuppressive drugs

In general, immunosuppressive drugs work by targeting the leukocytes, which function within the immune system to attack foreign bodies as well as produce an inflammatory response in reaction to bacteria and other disease organisms. Immunosuppressive drugs are used to reduce the number of leukocytes or interfere with their functioning in order to prevent transplant rejection or the inflammation characteristic of autoimmune diseases.

Immunosuppressive drugs can be categorized in several different ways:

- Glucocorticoids are the oldest type of immunosuppressive drug. These agents are a class of steroid hormone and work by regulating gene expression; that is, by suppressing genes that code for certain cytokines. This process in turn inhibits the activation of T cells. The glucocorticoids include cortisone, prednisolone, prednisone, methylprednisolone, dexamethasone, and fludrocortisone.
- Cytostatic drugs work by inhibiting cell division and proliferation. They include alkylating agents like nitrogen mustard (cyclophosphamide or Cytoxan), which attack the DNA of targeted cells, and antimetabolites like azathioprine and mercaptopurine, which inhibit cell division by interfering with DNA synthesis. Methotrexate is another immunosuppressive drug that is classified as an antimetabolite because it interferes with the metabolism of folic acid.
- Antibodies, also called protein immunosuppressive drugs, include both polyclonal antibodies and monoclonal antibodies. Polyclonal antibodies are derived from the serum of horses or rabbits and are injected with human lymphocytes; the most commonly used are Atgam, derived from horse serum, and thymoglobulin, derived from rabbit serum. Polyclonal antibodies carry a high risk of serum sickness and other severe reactions. Monoclonal antibodies are less likely to cause severe reactions because they are derived from identical immune cells cloned from a single parent cell. These drugs include basiliximab, rituximab (Rituxan), and daclizumab, which work by inhibiting interleukins on activated T cells, thereby helping to prevent acute rejection of transplanted kidneys. Intravenous immune globulin is also classified as a protein immunosuppressive drug.
- Small-molecule immunosuppressive agents include the calcineurin inhibitors, which work to counteract calcineurin, a protein compound that activates T cells. The calcineurin inhibitors include cyclosporine (Sandimmune), tacrolimus (Prograf), and sirolimus (Rapamune). A second type of small-molecule agent includes drugs that inhibit nucleotide synthesis. Nucleotides are the molecules that form the building blocks of DNA and RNA. Drugs that inhibit nucleotide synthesis include mycophenolate mofetil, mycophenolic acid (MCA or Myfortic), mizoribine (Bredinin), leflunomide (Arava), and FK778. Leflunomide is also classified as a disease-modifying antirheumatic drug (DMARD) and is used to treat rheumatoid arthritis as well as prevent transplant rejection. FK778 is a derivative of leflunomide that is presently in clinical trials to prevent kidney rejection.

STAGES OF IMMUNOSUPPRESSIVE DRUG THERAPY. Patients receiving immunosuppressive drugs to prevent the rejection of a transplanted organ typically undergo three stages or phases of treatment with these drugs: induction, maintenance, and antirejection.

The induction phase of treatment consists of intensified doses of a steroid immunosuppressant along with a monoclonal antibody and a thymoglobulin. These drug combinations are intended to prevent acute transplant rejection, which develops within days to weeks after transplantation when T cells in the recipient's adaptive immune system encounter the transplanted tissue and release cytokines (cell-signaling molecules) that lead to insufficient vascular supply and the destruction of cells in the new organ. A common combination of immunosuppressive drugs in the induction phase uses methylprednisolone (Solu-Medrol), Atgam, and basiliximab (Simulect) or daclizumab (Zenapax). Although these drugs may be given to the patient for longer than the first 30 days after **transplant surgery**, they are not used for long-term therapy. Newer protocols for kidney transplant patients recommend withdrawing steroid immunosuppressants as soon as possible.

Maintenance immunosuppressive drugs may be given before or during transplantation as well as after to minimize the risk of organ rejection. These immunosuppressants are intended to be given long-term and do not include any of the drugs given during the induction phase. They may include prednisone,

WWW.BOOKBAZ.IR

cyclosporine, tacrolimus, azathioprine, mycophenolate mofetil, or rapamycin (Rapamune).

Many transplant patients will experience an episode of acute rejection, most often within the first three months after the procedure. A single episode of acute rejection can usually be successfully treated without failure of the transplanted organ, but recurrent episodes may lead to chronic rejection, in which the transplanted organ undergoes long-term loss of function. The drugs given to treat an episode of acute rejection are the same as those used in the induction phase.

Chronic transplant rejection is generally considered irreversible, with a new transplant being the most common treatment. An inhaled form of cyclosporine is under investigation as a treatment for chronic rejection of transplanted lungs.

Other forms of immunosuppression

RADIATION THERAPY. Radiation therapy, one of the earliest forms of immunosuppression, is still used together with immunosuppressive drugs to kill cancer cells in patients awaiting bone marrow transplant. It is occasionally used to treat patients with autoimmune disorders who develop cancer.

PLASMAPHERESIS. Plasmapheresis is a form of treatment used in certain autoimmune disorders that involves the withdrawal of the patient's blood through an implanted catheter, the separation of the plasma (the liquid portion of the blood) from the red and white blood cells, and the reinfusion of the blood cells back into the patient's body. The reason for removing the blood plasma is that plasma carries the autoantibodies responsible for symptoms of such autoimmune disorders as **myasthenia gravis**, Guillain-Barré syndrome, Behçet's disease, Goodpasture's syndrome, Wegener's granulomatosis, and others. In many cases, plasmapheresis is used together with immunosuppressive drugs rather than as a stand-alone therapy.

SPLENECTOMY. Splenectomy is the surgical removal of the spleen, a small organ about 4 in. (10 cm) long located in the left upper quadrant of the abdomen in humans. The spleen serves to filter the blood, removing old red blood cells (RBCs), other defective blood cells, and bacteria from circulation. It also stores RBCs that can be released in an emergency, as well as platelets (cell fragments that play a role in blood clotting) and lymphocytes. As much as 25% of the body's lymphocytes can be stored in the spleen at any given time. The spleen may be removed surgically if traumatic injury causes it to rupture; to treat lymphomas or the spread of **stomach cancer**; to treat disorders of the blood characterized by the presence of abnormal blood cells; or to treat **idiopathic thrombocytopenic purpura** (ITP), an autoimmune disorder characterized by a low **platelet count** in the absence of a disorder of the bone marrow. ITP is treated first with **corticosteroids** and immunosuppressive drugs like rituximab, with a splenectomy performed only when medical therapy fails.

Immunosuppression, whether it involves drugs, surgery (splenectomy), or radiation therapy, requires a large healthcare team. Plasmapheresis usually requires a hematologist (blood specialist) and a rheumatologist to oversee the care of a patient with an autoimmune disorder, as well as a nurse to assist with the procedure and help with patient education. It is typically performed in a hospital. Radiation therapy involves a radiologist and radiologic technologist and is also performed in a hospital. A splenectomy is performed in a hospital by a surgeon and anesthesiologist, as the patient must be placed under general **anesthesia**.

Immunosuppressive medications for transplant patients are started in the hospital, either before, during, or shortly after surgery. The transplant surgeon is usually involved in the selection of medications, as are other physicians who specialize in kidney, heart, lung, or blood disorders, depending on the organ being transplanted. Nurses generally administer the medication and monitor the patient for adverse effects. Nurses and pharmacists may be involved in patient education regarding the specific medications prescribed, potential side effects, risks of interactions with other drugs, and any other information the patient may require. Maintenance immunosuppression is carried out by the patient at home, taking the immunosuppressive drugs (usually by mouth) as directed. Scheduling the doses is often complex and may require a chart, timer, or other device to remind the patient to take the correct medication at the proper time. The patient will return to the doctor's office or a hospital outpatient clinic for periodic blood tests, tissue biopsies, and other studies.

Other healthcare professionals who may be involved in the care of patients receiving immunosuppression therapy include psychologists or psychiatrists, to evaluate **anxiety** or depression related to immunosuppressive medications; dietitians, to recommend dietary modifications; social workers, to assist with financial issues; and physical or respiratory therapists, to recommend exercises to assist the patient in returning to normal levels of physical activity.

Preparation

Preparation for immunosuppressive treatment for organ transplant patients is part of a lengthy process. Evaluation begins with determining whether an organ transplant is right for the individual patient. That assessment includes not only a **physical examination**, blood tests and **tissue typing**, and imaging studies, but also a psychological and social evaluation. This is done because immunosuppressive treatment is not only financially costly, but can also place **stress** on the patient's family due to the measures needed to protect the patient against infection, the need for frequent blood tests and other checkups, and the potential side effects of the **immunosuppressant drugs**.

Preparation for immunosuppressive treatment also requires intensive patient education. Because most patients are treated with a combination of drugs, or with radiation therapy or splenectomy in addition to immunosuppressive drugs, it is essential for patients to understand the characteristics and potential side effects of the drugs prescribed for them, as well as the importance of compliance with their drug regimen. Noncompliance with immunosuppressive medications is one of the most common reasons for the failure of organ transplants; it is estimated to be as high as 50% among adolescent recipients of organ transplants. Patients should be instructed to report severe side effects to their doctor(s) and never stop taking the medications without the consent of their physician.

Aftercare

Immediate aftercare following an organ transplant requires the patient to remain in the clinic or hospital where the transplant was performed for several weeks following the procedure. The length of stay varies according to the specific organ that was transplanted and the patient's overall health. The patient receives daily blood tests and checkups for infections in order to monitor the effectiveness of the immunosuppression. Because acute rejection is most likely to occur during the first three months after transplantation, patients who have returned home should keep in close contact with the hospital in case their immunosuppressive drugs need to be changed or the dosage altered.

Short-term aftercare at home includes continuing to take prescribed drugs and taking additional measures to reduce the risk of infection. The United Network for Organ Sharing (UNOS) recommends taking the following precautions for the first few months after surgery:

- Avoid crowded places such as shopping malls, sports arenas, busy restaurants, theaters, and churches.
- Avoid touching or cuddling household pets, and ask other family members to take care of the pet's food, veterinary care, and other needs.
- Avoid contact with anyone known to have an active infection or contagious illness.
- Avoid working in the garden; garden soil and plants are a common source of infectious organisms.
- Avoid buildings under construction or demolition.
- Wash hands frequently and cleanse even minor scrapes or cuts thoroughly.
- Contact the doctor promptly at any sign of infection (fever, pain, redness, or swelling) in an injury.
- Maintain good dental care and see the dentist regularly for checkups.

Longer-term maintenance care includes ongoing compliance with taking immunosuppressive drugs as well as periodic blood tests, tissue biopsies, lung function tests, ultrasounds, and any other tests that may be ordered to evaluate the side effects of the drugs and the functioning of the organ. Patients are typically asked to monitor their own blood pressure, pulse rate, weight, and temperature at home on a daily basis. Patients may also require **psychotherapy** or counseling in order to cope with the social and psychological effects of immunosuppressive therapy, as well as the physical stress.

Longer-term maintenance care may also involve changes in the specific combination of immunosuppressant drugs used due to decreasing effectiveness, the severity of side effects, or the introduction of a promising new drug.

Risks

Immunosuppressive drugs carry four major risks, which are:

- Side effects. The side effects of immunosuppressive drugs can be troublesome and are a major reason for patient noncompliance. Because all immunosuppressant drugs work by targeting white blood cells, even those that are directed at only one phase of white blood cell production or activity typically affect other biochemical processes within the immune system. About 30 different side effects have been reported, including anemia, acne, "moon face" (round, puffy face), headaches, increased appetite, higher blood sugar or blood cholesterol levels, weight gain, gout, fat deposits around the back of the neck, hair loss, kidney damage, anxiety, mood swings, insomnia, skin peeling on hands and feet, nausea, vomiting, diarrhea, increased sensitivity to sun exposure, and tingling sensations in the hands and feet.

WWW.BOOKBAZ.IR

KEY TERMS

Adaptive immune system—The part of the immune system that develops responses to specific antigens and maintains immunological memory. It is also known as the acquired immune system.

Antibody—A protein produced by the immune system in response to the presence of an antigen (a foreign substance or organism).

Antimetabolite—An immunosuppressive drug that works by interfering with a cell's use of a metabolite (a byproduct of normal metabolism). Antimetabolites inhibit the growth and division of cells.

Autoimmune disorders—A group of disorders caused by inappropriate responses of the body's immune system to substances, organs, or tissues normally present in the body.

B cell—A type of small-cell lymphocyte that belongs to the adaptive immune system. B cells function to make antibodies against specific antigens.

Cytokine—Any of a group of signaling molecules, including interleukin, interferon, and tumor necrosis factor, that influence the functioning of the immune system and may have either pro- or anti-inflammatory effects.

Cytostatic drug—Any drug that inhibits or prevents cell division and proliferation.

Innate immune system—The part of the immune system that responds to infectious organisms in a nonspecific manner. Natural killer cells are part of the innate immune system.

Interleukin—Any of a group of cytokines that were first found to be expressed by white blood cells and help to regulate the responses of the immune system.

Leukocyte—A general term for the various types of white blood cells in the immune system that protect the body against infectious disease agents and foreign substances. Immunosuppressive drugs reduce the number and activity of leukocytes.

Lymphocyte—A type of leukocyte or white blood cell with a large nucleus that functions in both the innate and adaptive immune systems. Lymphocytes account for about one-third of all white blood cells and include B cells, T cells, and NK cells.

Monoclonal antibody—A type of antibody produced by identical immune cells derived by cloning

- Increased risk of infections. Immunosuppressive drugs increase a patient's susceptibility to bacterial, viral, and fungal infections. According to UNOS, the most common infections in transplant patients during the first month after surgery are urinary tract infections, wound infections, infections surrounding intravenous lines, and pneumonia. Between the first month and the sixth month, the most common infections are pneumonia, Epstein-Barr virus, cytomegalovirus (CMV), and infections of the central nervous system. After the sixth month, the patient is at increased risk of opportunistic infections and hepatitis B or C.
- Increased risk of developing cancer. As early as 1957, a team of British physicians proposed that lymphocytes, a type of white blood cell that includes T cells, B cells, and natural killer cells, act as sentinels to prevent abnormal cells from developing into cancers. This function of lymphocytes is known as cancer immunosurveillance. The ability of lymphocytes to act as an early warning system to protect against cancer is disrupted by immunosuppressive medications. As a result, persons receiving these drugs for autoimmune disorders as well as organ transplants are at increased risk of cancer in later life.
- Interactions with other medications. Because immunosuppressive drugs are powerful compounds with many side effects, they interact with a large number of over-the-counter (OTC) as well as prescription medications, including antidepressants, antiretroviral drugs (used to treat HIV infection), antifungal medications, antibiotics, blood pressure medications, antacids, antiseizure medications, cholesterol-lowering drugs, androgens (male sex hormones), estrogens (female sex hormones), and others. Because of the potential for severe drug interactions, patients receiving immunosuppressive drugs should give their doctor(s) a complete list of all medications they take regularly, including nonprescription medications like aspirin or cold medicines as well as prescription drugs.

Plasmapheresis

Patients being treated with plasmapheresis are at risk of:

- infection from the catheter used to withdraw the blood
- blood clotting disorders resulting from the chemicals used to prevent the blood from clotting during the plasmapheresis procedure

a unique parent cell. The generic names on monoclonal antibody drugs all end in –mab.

Natural killer (NK) cell—A large-celled lymphocyte that functions as part of the innate immune system to respond to cells infected by viruses and tumor cells.

Nucleotides—Small molecules that form the building blocks of DNA and RNA, play important roles in cell metabolism, and participate in cell signaling.

Opportunistic infection—An infection caused by a bacterium, virus, fungus, or protozoon that would not cause disease in a person with a normally functioning immune system.

Plasmapheresis—A procedure in which blood is withdrawn from a patient's circulation, the plasma is separated from the blood cells, and the cells are returned to the patient's bloodstream. It may be used alongside immunosuppressive drugs in the treatment of autoimmune disorders.

Platelets—Small disk-shaped components found in blood that lack cell nuclei and are associated with the process of blood clotting.

Protocol—A set of guidelines for a patient's therapy; a treatment plan.

Regenerative medicine—A new branch of medicine that investigates ways to restore damaged tissues or organs by replacing them with new ones derived from the patient's stem cells, or by stimulating the body's own repair mechanisms to heal damaged organs.

Serum sickness—An inflammatory reaction in humans to proteins in serum derived from animal sources that contain polyclonal antibodies. It develops 4–10 days after exposure and is characterized by fever, joint pain, itching, rashes, low blood pressure, an enlarged spleen, and protein and blood in the urine.

Splenectomy—Surgical removal of the spleen.

T cell—A type of small-cell lymphocyte that is part of the adaptive immune system. There are several types of T cells with different functions: to assist other lymphocytes; to destroy tumor cells; to provide the immune system with "memory" of past infections; and to modulate the immune system so as to provide protection against autoimmune disease.

- transfusion reactions
- low blood calcium levels, again due to the addition of chemicals to prevent blood clotting

Radiation therapy

Patients treated with radiation therapy as a form of immunosuppression often experience a range of side effects, including skin disorders, nausea, hair loss, **infertility**, and fluid retention.

Splenectomy

Patients who have had their spleen removed are at increased risk of infection, particularly in the first two years after surgery. These infections may develop suddenly and become life-threatening; they are referred to as overwhelming post-splenectomy infections (OPSI). OPSI has a mortality rate close to 50%. Patients treated with a combination of splenectomy and corticosteroids may develop such side effects as **osteoporosis**, **glaucoma**, **cataracts**, and loss of muscle mass.

Alternative therapies

Patients should not use alternative therapies in place of immunosuppressive agents. They should also avoid using herbal remedies when taking immunosuppressive drugs, as some herbs interact with these drugs. Alternative treatments that involve physical contact with a practitioner, such as **massage therapy**, **chiropractic**, or bodywork, should also be avoided because of the risk of infection. On the other hand, such complementary practices as **meditation**, prayer, **guided imagery**, relaxation therapy, **music therapy**, or **art therapy** may help to ease the stresses associated with immunosuppression. After the patient has returned home and is on maintenance levels of medication, gentle forms of **exercise** like tai chi, stretching exercises, and **yoga** may be undertaken with the doctor's supervision.

Results

Normal results for immunosuppressant therapies include the avoidance of acute rejection for organ transplants and the relief of symptoms of autoimmune disorders.

WWW.BOOKBAZ.IR

Abnormal results of immunosuppression therapies include acute or opportunistic infections, rejection of an organ transplant, unusually severe side effects, toxic **drug interactions**, and cancer.

Alternatives

At present there are no effective alternatives to immunosuppression in organ transplantation or autoimmune disorders in most cases. However, regenerative medicine, a new branch of medicine, offers some hope for the future. Regenerative medicine investigates stem **cell therapy**, tissue engineering, and similar approaches to develop new tissues and possibly entire organs from patients' stem cells that could be used to replace failing body parts without the risk of rejection.

Immunotherapy *see* **Immunologic therapies**

KEY TERMS

Dry socket—A painful condition following tooth extraction in which a blood clot does not properly fill the empty socket, leaving the bone underneath exposed to air and food.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Extraction—The removal of a tooth from its socket in the bone.

Pericoronitis—A gum condition in which irritation and inflammation are produced by the crown of an incompletely erupted tooth.

Wisdom tooth—One of the four last teeth on the top and bottom rows of teeth. Also called a third molar.

Impacted tooth

Definition

An impacted tooth is any tooth that is prevented from reaching its normal position in the mouth by tissue, bone, or another tooth.

Description

The teeth that most commonly become impacted are the third molars, also called wisdom teeth. These large teeth are the last to develop, beginning to form when a person is about nine years old, but not breaking through the gum tissue until the late teens or early twenties. By this time, the jaws have stopped growing and may be too small to accommodate these four additional teeth. As the wisdom teeth continue to move, one or more may become impacted, either by running into the teeth next to them or becoming blocked within the jawbone or gum tissue. An impacted tooth can cause further dental problems, including infection of the gums, displacement of other teeth, or decay. At least one wisdom tooth becomes impacted in nine of every ten people.

Causes and symptoms

The movement of an erupting wisdom tooth and any subsequent impaction may produce **pain** at the back of the jaw. Pain may also be the result of infection, either from decay in any exposed portion of the tooth or from trapped food and plaque in the surrounding gum tissue. Infection typically produces an unpleasant taste when biting down and **bad breath**. Another source of pain may be pericoronitis, a gum condition in which the crown of the incompletely erupted tooth produces inflammation, redness, and tenderness of the gums. Less common symptoms of an impacted tooth are swollen lymph nodes in the neck, difficulty opening the mouth, and prolonged **headache**.

Diagnosis

Upon visual examination, the dentist may find signs of infection or swelling in the area where the tooth is present or only partially erupted. Dental x rays are necessary to confirm tooth impaction.

Treatment

Because impacted teeth may cause dental problems with few, if any, symptoms to indicate damage, dentists commonly recommend the removal of all wisdom teeth, preferably while the patient is still a young adult. A dentist may perform an extraction with forceps and local anesthetic if the tooth is exposed and appears to be easily removable in one piece. However, he or she may refer a difficult extraction to an oral surgeon, a specialist who administers either nitrous oxide-oxygen (commonly called "laughing gas"), an intravenous sedative, or a general anesthetic to alleviate any pain or discomfort during the surgical procedure. Extracting an impacted tooth

WWW.BOOKBAZ.IR

typically requires cutting through gum tissue to expose the tooth, and may require removing portions of bone to free the tooth. The tooth may have to be removed in pieces to minimize destruction to the surrounding structures. The extraction site may or may not require one or more stitches to help the incision heal.

Prognosis

The prognosis is very good when impacted teeth are removed from young healthy adults without complications. Potential complications include post-operative infection, temporary numbness from nerve irritation, jaw fracture, and jaw joint pain. An additional condition that may develop is called dry socket: when a blood clot does not properly form in the empty tooth socket, or is disturbed by an oral vacuum (such as from drinking through a straw or **smoking**), the bone beneath the socket is painfully exposed to air and food, and the extraction site heals more slowly.

Bethany Thivierge

Impedance phlebography

Definition

Impedance phlebography is a noninvasive test that uses electrical monitoring to measure blood flow in veins of the leg. Information from this test helps a doctor to detect **deep vein thrombosis** (**blood clots** or **thrombophlebitis**).

Purpose

Impedance phlebography may be done in order to:

- detect blood clots lodged in the deep veins of the leg
- screen patients who are likely to have blood clots in the leg
- detect the source of blood clots in the lungs (pulmonary emboli)

Blood clots in the legs can lead to more serious problems. If a clot breaks loose from a leg vein, it may travel to the lungs and lodge in a blood vessel in the lungs. Blood clots are more likely to occur in people who have recently had leg injuries, surgery, cancer, or a long period of bed rest.

Precautions

Because this test is not invasive, it can be done on all patients. However, the accuracy of the results will be affected if the patient does not breathe normally or keep the leg muscles relaxed. Compression of the veins because of pelvic tumors or decreased blood flow, due to **shock** or any condition that reduces the amount of blood the heart pumps, may also change the test results.

Description

Impedance phlebography works by measuring the resistance to the transmission of electrical energy (impedance). This resistance changes depending on the volume of blood flowing through the veins. By graphing the impedance, a doctor or technician can tell whether a clot is obstructing blood flow.

Using conductive jelly, the examiner puts electrodes on the patient's calf. These electrodes are connected to an instrument called a plethysmograph, which records the changes in electrical resistance that occur during the test.

The patient lies down and raises one leg at a 30° angle, so that the calf is above the level of the heart. The examiner wraps a pressure cuff around the patient's thigh and inflates it to a pressure of 18–24 in. (45–60 cm) of water for 45 seconds. The plethysmograph records the electrical changes that correspond to changes in the volume of blood in the vein at the time the pressure is exerted and again three seconds after the cuff is deflated. This procedure is repeated several times in both legs.

This test takes 30–45 minutes. Impedance phlebography is also called an impedance test of blood flow or impedance plethysmography.

Preparation

Patients undergoing this test do not need to alter their diet, change their normal activities, or stop taking any medications. They will wear a surgical gown during the test, and be asked to urinate before the test starts. If keeping the legs elevated causes discomfort, mild **pain** medication will be given.

KEY TERMS

Thrombophlebitis—Inflammation of a vein, associated with the formation of a blood clot.

Aftercare

The patient may resume normal or postoperative activities after the test.

Risks

Impedance phlebography is painless and safe. It presents no risk to the patient.

Results

Normally, inflating the pressure cuff will cause a sharp rise in the pressure in the veins of the calf because blood flow is blocked. When the cuff is released, the pressure decreases rapidly as the blood flows away.

Abnormal results

If a clot is present, the pressure in the calf veins will already be high. It does not become sharply higher when the pressure cuff is tightened. When the pressure cuff is deflated, the clot blocks the flow of blood out of the calf vein. The decrease in pressure is not as rapid as when no clot is present, and the shape of the resulting graph is different.

Impedance test of blood flow *see* **Impedance phlebography**

Impetigo

Definition

Impetigo refers to a very localized bacterial infection of the skin. There are two types, bullous and epidemic.

Description

Impetigo is a skin infection that primarily afflicts children. Impetigo caused by the bacterium *Staphylococcus aureus* (also known as staph) affects children of all ages. Impetigo caused by the bacteria called group A streptococci (also know as strep) are most common in children ages two to five.

The bacteria that cause impetigo are very contagious. They can be spread by a child from one part of his or her body to another by scratching, or contact with a towel, clothing, or stuffed animal. These same methods can pass the bacteria on from one person to another.

Impetigo tends to develop in areas of the skin that have already been damaged through some other mechanism (a cut or scrape, burn, insect bite, or vesicle from **chickenpox**).

Causes and symptoms

The first sign of bullous impetigo is a large bump on the skin with a clear, fluid-filled top (called a vesicle). The bump develops a scab-like, honey-colored crust. There is usually no redness or **pain**, although the area may be quite itchy. Ultimately, the skin in this area will become dry and flake away. Bullous impetigo is usually caused by staph bacteria.

Epidemic impetigo can be caused by staph or strep bacteria, and (as the name implies) is very easily passed among children. Certain factors, such as heat and humidity, crowded conditions, and poor hygiene increase the chance that this type of impetigo will spread rapidly among large groups of children. This type of impetigo involves the formation of a small vesicle surrounded by a circle of reddened skin. The vesicles

Impetigo is a contagious bacterial skin infection that mostly affects the area around the nose and mouth. Usually caused by staphylococci, this person's impetigo was triggered by herpes simplex. *(Photo Researchers, Inc.)*

WWW.BOOKBAZ.IR

KEY TERMS

Systemic—Involving the whole body; the opposite of localized.

Ulcer—An irritated pit in the surface of a tissue.

Vesicle—A bump on the skin filled with fluid.

appear first on the face and legs. When a child has several of these vesicles close together, they may spread to one another. The skin surface may become eaten away (ulcerated), leaving irritated pits. When there are many of these deep, pitting **ulcers**, with pus in the center and brownish-black scabs, the condition is called ecthyma. If left untreated, the type of bacteria causing this type of impetigo has the potential to cause a serious **kidney disease** called **glomerulonephritis**. Even when impetigo is initially caused by strep bacteria, the vesicles are frequently secondarily infected with staph bacteria.

Impetigo is usually an uncomplicated skin condition. Left untreated, however, it may develop into a serious disease, including **osteomyelitis** (bone infection), septic arthritis (joint infection), or **pneumonia**. If large quantities of bacteria are present and begin circulating in the bloodstream, the child is in danger of developing an overwhelming systemic infection known as **sepsis**.

Diagnosis

Characteristic appearance of the skin is the usual method of diagnosis, although fluid from the vesicles can be cultured and then examined in an attempt to identify the causative bacteria.

Treatment

Uncomplicated impetigo is usually treated with a topical antibiotic cream called mupirocin. In more serious, widespread cases of impetigo, or when the child has a **fever** or **swollen glands**, **antibiotics** may be given by mouth or even through a needle placed in a vein (intravenously).

Prognosis

Prognosis for a child with impetigo is excellent. The vast majority of children recover quickly, completely, and uneventfully.

Prevention

Prevention involves good hygiene. Handwashing; never sharing towels, clothing, or stuffed animals; and keeping fingernails well-trimmed are easy precautions to take to avoid spreading the infection from one person to another.

Implant therapy *see* **Radioactive implants**

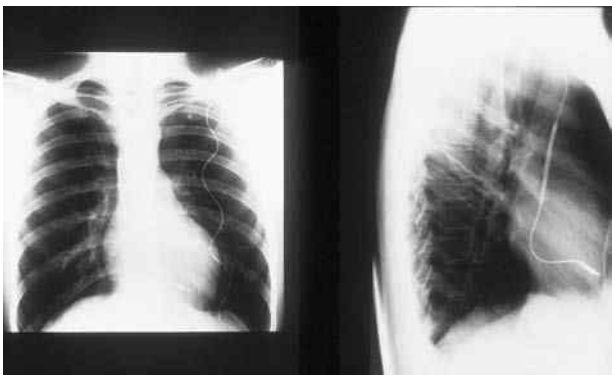
Implantable cardioverter defibrillator

Definition

The **implantable cardioverter defibrillator** (ICD) is a surgically implanted electronic device that directs an electric charge directly into the heart to treat life-threatening **arrhythmias**.

Purpose

The ICD is used to detect and stop life-threatening arrhythmias and restore a productive heartbeat that is able to provide adequate cardiac output to sustain life. The exact indications for the implantation of the device are controversial, but patients with **ventricular fibrillation** (unproductive heartbeat), **ventricular tachycardia** (abnormally fast heartbeat), long QT syndrome (an inherited **heart disease**), or others at risk for **sudden cardiac death** are potential candidates for this device. A study by the National Institute for Heart, Lung, and Blood of the National Institutes of Health showed a significant increase in survival for patients with ventricular arrhythmias when ICD implant is compared to medication. Several follow-up studies indicate that this may be due to the marked increase in survival for the sickest patients, generally defined as those having a heart weakened to less than 50% of normal, as measured by the ability of the left side of the heart to pump blood. Overall, studies have documented a very low mortality rate of 1–2% annually for persons implanted with the device, compared to approximately 15–25% for patients on drug therapy.



X ray of implanted cardioverter-defibrillator. *(Custom Medical Stock Photo, Inc.)*

Demographics

ICD implant is limited to patients that face the risk of sudden cardiac death from sustained ventricular arrhythmia, including ventricular tachycardia and ventricular fibrillation. Less than 1% of the more than 100,000 device implants done in the United States are performed on pediatric patients. Reduction in the risk of sudden cardiac death improves to less than 2% for both populations.

Diagnosis

Patients experiencing syncope (**fainting**) will be monitored with a cardiac monitor for arrhythmias. Following unsuccessful medical treatment for sustained ventricular arrhythmias, ICD implant will be indicated.

Description

Similar in structure to a pacemaker, an ICD has three main components: a generator, leads, and an electrode. The generator is encased in a small rectangular container, usually about 2 in. (5 cm) wide and around 3 oz. (85 g) in weight. Even smaller generators have been developed, measuring 1 in. (2.5 cm) in diameter and weighing about 0.5 oz. (14 g). The generator is powered by lithium batteries and is responsible for generating the electric shock. The generator is controlled by a computer chip that can be programmed to follow specific steps according to the input gathered from the heart. The programming is initially set and can be changed using a wand programmer, a device that communicates by radio waves through the chest of the patient after implantation. One or two leads, or wires, are attached to the generator. These wires are generally made of platinum with an insulating coating of either silicone or polyurethane. The leads carry the electric shock from the generator. At the tip of each lead is a tiny device called an electrode that delivers the necessary electrical shock to the heart. Thus, the electric shock is created by the generator, carried by the leads, and delivered by the electrodes to the heart. The decision of where to put the leads depends on the needs of the patient, but they can be located in the left ventricle, the left atrium, or both.

According to the American College of Cardiology, more than 100,000 persons worldwide currently have an ICD. The battery-powered device rescues the patient from a life-threatening arrhythmia by performing a number of functions in order to reestablish normal heart rhythm, which varies with the particular problem of the patient. Specifically, if encountered with ventricular tachycardia, many devices will begin treatment with a pacing regimen. If the tachycardia is not too fast, the ICD can deliver several pacing signals in a row. When those signals stop, the heart may go back to a normal rhythm. If the pacing treatment is not successful, many devices will move onto **cardioversion**. With cardioversion, a mild shock is sent to the heart to stop the fast heartbeat. If the problem detected is ventricular fibrillation, a stronger shock called a **defibrillation** is sent. This stronger shock can stop the fast rhythm and help the heartbeat return to normal. Finally, many ICDs can also detect heartbeats that are too slow; they can act like a pacemaker and bring the heart rate up to normal. ICDs that defibrillate both the ventricles and the atria have also been developed. Such devices not only provide dual-chamber pacing but also can distinguish ventricular from **atrial fibrillation**. Patients that experience both atrial and ventricle fibrillations, or atrial fibrillation alone, that would not be controlled with a single-chamber device are candidates for this kind of ICD.

Operation

ICD insertion is considered minor surgery, and can be performed in either an operating room or an electrophysiology laboratory. The insertion site in the chest will be cleaned, shaved, and numbed with local anesthetic. Generally, left-handed persons have ICDs implanted on the right side, and vice versa, to speed return to normal activities. Two small cuts (incisions) are made, one in the chest wall and one in a vein just under the collarbone. The wires of the ICD are passed through the vein and attached to the inner surface of the heart. The other ends of the wires are connected to the main box of the ICD, which is inserted into the tissue under the collarbone and above the breast. Once the ICD is implanted, the physician will test it several

WWW.BOOKBAZ.IR

KEY TERMS

Arrhythmia—A variation of the normal rhythm of the heartbeat.

Cardioverter—A device to apply electric shock to the chest to convert an abnormal heartbeat into a normal heartbeat.

Defibrillation—An electronic process that helps reestablish a normal heart rhythm.

Ventricles—The two large lower chambers of the heart that pump blood to the lungs and the rest of the human body.

Ventricular fibrillation—An arrhythmia in which the heart beats very fast, but blood is not pumped out to the body, which can become fatal if not corrected.

Ventricular tachycardia—An arrhythmia in which the heart rate is more than 100 beats per minute.

times before the **anesthesia** wears off by causing the heart to fibrillate and making sure the ICD responds properly. The doctor then closes the incision with sutures (stitches), staples, or surgical glue. The entire procedure takes about an hour.

Immediately following the procedure, a **chest x-ray** will be taken to confirm the proper placement of the wires in the heart. The ICD's programming may be adjusted by passing the programming wand over the chest. After the initial operation, the physician may induce ventricular fibrillation or ventricular tachycardia one more time prior to the patient's discharge, although recent studies suggest that this final test is not generally necessary.

A short stay in the hospital is usually required following ICD insertion, but this varies with the patient's age and condition. If there are no complications, complete recovery from the procedure will take about four weeks. During that time, the wires will firmly take hold where they were placed. In the meantime, the patient should avoid heavy lifting or vigorous movements of the arm on the side of the ICD, or else the wires may become dislodged.

After implantation, the cardioverter defibrillator is programmed to respond to rhythms above the patient's **exercise** heart rate. Once the device is in place, many tests will be conducted to ensure that the device is sensing and defibrillating properly. About 50% of patients with ICDs require a combination of drug therapy and the ICD.

Electrophysiologists are specially trained cardiologists or thoracic surgeons who study and treat problems with the heart conduction system. In a hospital operating room, they often implant the ICD system and oversee the programming or reprogramming of the device. Electrophysiologists receive special continuing medical education to provide successful implantation. Implantation, follow-up, and replacement can be limited at any one institution, therefore, an experienced well-trained electrophysiologist should perform these procedures.

Aftercare

In general, if the condition of the patient's heart, drug intake, and metabolic condition remain the same, the ICD requires only periodic checking every two months or so for battery strength and function. This is done by placing a special device over the ICD that allows signals to be sent over the telephone to the doctor, a process called trans-telephonic monitoring.

If changes in medications or physical condition occur, the doctor can adjust the ICD settings using a programmer, which involves placing the wand above the pacemaker and remotely changing the internal settings. One relatively common problem is the so-called "ICD storm," in which the machine inappropriately interprets an arrhythmia and gives a series of shocks. Reprogramming can sometimes help alleviate that problem.

When the periodic testing indicates that the battery is getting low, an elective ICD replacement operation is scheduled. The entire signal generator is replaced because the batteries are sealed within the case. The leads can often be left in place and reattached to the new generator. Batteries usually last 4–8 years.

Results

Ventricular tachycardia can be successfully relieved by pacing in 96% of instances with the addition of defibrillation converting 98% of patients to a productive rhythm that is able to sustain cardiac output. Ventricular fibrillation is successfully converted in 98% of all cases. Atrial fibrillation and rapid ventricular response leads to erroneous fibrillation in as many as 11% of patients.

Morbidity and mortality rates

Perioperative mortality demonstrates a 0.4–1.8% risk of death for primary nonthoracotomy implants. The ICD showed improved survival compared to medical therapy, improving by 38% at one year. There is a 96% survival rate at four years for those implanted

with ICD. Less then 2% of patients require termination of the device, with a return to only medical therapy.

Risks

Environmental conditions that can affect the functioning of the ICD after installation include:

- strong electromagnetic fields such as those used in arc-welding
- contact sports
- shooting a rifle from the shoulder nearest the installation site
- cell phones used on that side of the body
- magnetic mattress pads such as those believed to treat arthritis
- some medical tests such as magnetic resonance imaging (MRI)

Environmental conditions often erroneously thought to affect ICDs include:

- microwave ovens (The waves only affect old, unshielded pacemakers and do not affect ICDs.)
- airport security (Metal detector alarms could be set off, so patients should carry a card stating they have an ICD implanted.)
- antitheft devices in stores (Patients should avoid standing near the devices for prolonged periods.)

Patients should also be instructed to memorize the manufacturer and make of their ICD. Although manufacturing defects and recalls are rare, they do occur and a patient should be prepared for that possibility.

Alternatives

Patients are treated with medical therapy to reduce the chance of arrhythmia. This alternative has been shown to have a higher rate of sudden death when compared to ICD over the initial three years of treatment, but has not been compared at five years. If the site of ventricular tachycardia generation can be mapped by electrophysiology studies, the aberrant cells can be removed or destroyed. Less then 5% of patients die during this cell removal procedure.

Impotence

Definition

Impotence, often called **erectile dysfunction**, is the inability to achieve or maintain an erection long enough to engage in sexual intercourse.

Description

Under normal circumstances, when a man is sexually stimulated, his brain sends a message down the spinal cord and into the nerves of the penis. The nerve endings in the penis release chemical messengers, called neurotransmitters, that signal the corpora

WWW.BOOKBAZ.IR

cavernosa (the two spongy rods of tissue that span the length of the penis) to relax and fill with blood. As they expand, the corpora cavernosa close off other veins that would normally drain blood from the penis. As the penis becomes engorged with blood, it enlarges and stiffens, causing an erection. Problems with blood vessels, nerves, or tissues of the penis can interfere with an erection.

Causes and symptoms

It is estimated that up to 20 million American men frequently suffer from impotence and that it strikes up to half of all men between the ages of 40 and 70. Doctors used to think that most cases of impotence were psychological in origin, but they now recognize that, at least in older men, physical causes may play a primary role in 60% or more of all cases. In men over the age of 60, the leading cause is atherosclerosis, or narrowing of the arteries, which can restrict the flow of blood to the penis. Injury or disease of the connective tissue, such as Peyronie's disease, may prevent the corpora cavernosa from completely expanding. Damage to the nerves of the penis, from certain types of surgery or neurological conditions, such as Parkinson's disease or **multiple sclerosis**, may also cause impotence. Men with diabetes are especially at risk for impotence because of their high risk of both atherosclerosis and a nerve disease called **diabetic neuropathy**.

Certain types of blood pressure medications, antiulcer drugs, **antihistamines**, tranquilizers (especially before intercourse), antifungals (hetoconazole), antipsychotics, **antianxiety drugs**, and antidepressants, known as **selective serotonin reuptake inhibitors** (SSRIs, including Prozac and Paxil), can interfere with erectile function. **Smoking**, excessive alcohol consumption, and illicit drug use may also contribute. In rare cases, low levels of the male hormone testosterone may contribute to erectile failure. Finally, psychological factors, such as **stress**, guilt, or **anxiety**, may also play a role, even when the impotence is primarily due to organic causes.

Diagnosis

The doctor obtains a thorough medical history to find out about past pelvic surgery, diabetes, cardiovascular disease, **kidney disease**, and any medications the man may be taking. The **physical examination** should include a genital examination, a measurement of blood flow through the penis, hormone tests, and a glucose test for diabetes.

In some cases, nocturnal penile tumescence testing is performed to find out whether the man has erections while asleep. Healthy men usually have about four or five erections throughout the night. The man applies a device to the penis called a Rigiscan before going to bed at night, and the device can determine whether he has had erections. (If a man is able to have normal erections at night, this suggests a psychological cause for his impotence.)

Treatment

Years ago, the standard treatment for impotence was an implantable penile prosthesis or long-term **psychotherapy**. Although physical causes are now more readily diagnosed and treated, individual or marital counseling is still an effective treatment for impotence when emotional factors play a role. Other approaches are now available to treat the physical causes of impotence.

Medications

The first line and by far the most common treatment is with the prescription drug **sildenafil citrate**, sold under the brand name Viagra. An estimated 20 million prescriptions for the pill have been filled since it was approved by the FDA in March 1998. It is also the most effective treatment with a success rate of more than 60%. The drug boosts levels of a substance called cyclic GMP, which is responsible for widening the blood vessels of the penis. In clinical studies, Viagra produced headaches in 16% of men who took it, and other side effects included flushing, **indigestion**, and stuffy nose.

The primary drawback to Viagra, which works about an hour after it is taken, it that the FDA cautions men with **heart disease** or low blood pressure to be thoroughly examined by a physician before obtaining a prescription.

In 2002, two investigational drugs were announced to become available in the near future to also treat erectile dysfunction. Vardenafil and tadalafil both helped men who also had such conditions as diabetes, high blood pressure and benign prostatic hypertrophy. The drugs are now available via prescription.

Vardenafil and tadalafil belong to the same group of chemical compounds as sildenafil, namely phosphodiesterase type 5 (PDE-5) inhibitors. Some men cannot benefit from sildenafil or the two newer PDE-5 inhibitors because they have low levels of nitric oxide. British investigators reported in late 2002 that three different types of compounds are being studied as possible medications for men with low levels of nitric oxide. They are Rho-kinase inhibitors, soluble

guanylate cyclase activators, and nitric oxide-releasing PDE-5 inhibitors.

Other medications under investigation as treatments for impotence are topical agents. Topical means that they are applied externally to the skin rather than being injected or taken by mouth. If approved, these drugs would provide a noninvasive alternative for men who cannot take sildenafil or other oral medications for impotence.

Injection therapy involves injecting a substance into the penis to enhance blood flow and cause an erection. The Food and Drug Administration (FDA) approved a drug called alprostadil (Caverject) for this purpose in 1995. Alprostadil relaxes smooth muscle tissue to enhance blood flow into the penis. It must be injected shortly before intercourse. A similar drug that is sometimes used is papaverine, which has not yet been approved by the FDA for this use. Either drug may sometimes cause painful erections or **priapism** (uncomfortable, prolonged erections) that must be treated with a shot of epinephrine.

Alprostadil may also be administered into the urethral opening of the penis. In MUSE (medical urethral system for erection), the man inserts a thin tube the width of a vermicelli noodle into his urethral opening and presses down on a plunger to deliver a tiny pellet containing alprostadil into his penis. The drug takes about 10 minutes to work and the erection lasts about an hour. The main side effect is a sensation of **pain** and burning in the urethra, which can last 5–15 minutes.

Mechanical and surgical treatments

Another approach is vacuum therapy. The man inserts his penis into a clear plastic cylinder and uses a pump to force air out of the cylinder. This forms a partial vacuum around the penis, which helps to draw blood into the corpora cavernosa. The man then places a special ring over the base of the penis to trap the blood inside it. The only side effect with this type of treatment is occasional bruising if the vacuum is left on too long.

Implantable **penile prostheses** are usually considered a last resort for treating impotence. They are implanted in the corpora cavernosa to make the penis rigid without the need for blood flow. The semi-rigid type of prosthesis consists of a pair of flexible silicone rods that can be bent up or down. This type of device has a low failure rate but, unfortunately, it causes the penis to always be erect, which can be difficult to conceal under clothing.

The inflatable type of device consists of cylinders that are implanted in the corpora cavernosa, a fluid reservoir implanted in the abdomen, and a pump placed in the scrotum. The man squeezes the pump to move fluid into the cylinders and cause them to become rigid. (He reverses the process by squeezing the pump again.) While these devices allow for intermittent erections, they have a slightly higher malfunction rate than the silicon rods.

Men can return to sexual activity six to eight weeks after implantation surgery. Since implants affect the corpora cavernosa, they permanently take away a man's ability to have a natural erection.

In rare cases, if narrowed or diseased veins are responsible for impotence, surgeons may reroute the blood flow into the corpus cavernosa or remove leaking vessels. The success rate with these procedures has been very low, and they are still considered experimental.

Gene therapy

A newer investigational approach to the treatment of erectile dysfunction is **gene therapy**. Several preclinical studies have shown promise, but none of the gene-based strategies so far have yet been tested for safety.

Alternatives

A number of herbs have been promoted for treating impotence. The most widely touted herbs for this purpose are *Coryanthe yohimbe* (available by prescription as yohimbine, with the trade name Yocon) and gingko (*Gingko biloba*), although neither has been conclusively shown to help the condition in controlled studies. In addition, gingko carries some risk of abnormal blood clotting and should be avoided by men taking blood thinners such as coumadin. Other herbs promoted for treating impotence include true unicorn root (*Aletrius farinosa*), **saw palmetto** (*Serenoa repens*), **ginseng** (*Panax ginseng*), and Siberian ginseng (*Eleuthrococcus senticosus*). *Strychnos Nux vomica* has been recommended, especially when impotence is caused by excessive alcohol, cigarettes, or dietary indiscretions, but it can be very toxic if taken improperly, so it should be used only under the strict supervision of a physician trained in its use.

Prognosis

With proper diagnosis, impotence can nearly always be treated or managed successfully. Unfortunately, fewer than 10% of impotent men seek treatment.

WWW.BOOKBAZ.IR

KEY TERMS

Alprostadil—A smooth muscle relaxant sometimes injected into the penis or applied to the urethral opening to treat impotence.

Atherosclerosis—A disorder in which plaques of cholesterol, lipids, and other debris build up on the inner walls of arteries, narrowing them.

Corpus cavernosum (plural, corpora cavernosa)—One of two rods of spongy tissue in the penis that become engorged with blood in order to produce an erection.

Gene therapy—A method of treating a disorder by replacing damaged or abnormal genes with normal ones. Some researchers think that gene therapy may offer a new way to treat impotence.

Neurotransmitters—Chemicals that modify or help transmit impulses between nerve synapses.

Papaverine—A smooth muscle relaxant sometimes injected into the penis as a treatment for impotence.

Peyronie's disease—A disease resulting from scarring of the corpus cavernosa, causing painful erections.

Topical—A type of medication that is applied to a specific and limited area of skin, and affects only the area to which it is applied.

Urethra—The small tube that drains urine from the bladder, as well as serving as a conduit for semen during ejaculation in men.

Viagra—Trade name of an orally administered drug for erectile failure first cleared for marketing in the United States in March 1998. Its generic name is sildenafil citrate.

Prevention

There is no specific treatment to prevent impotence. Perhaps the most important measure is to maintain general good health and avoid atherosclerosis by exercising regularly, controlling weight, controlling **hypertension** and high **cholesterol** levels, and avoiding smoking. Avoiding excessive alcohol intake may also help.

Impulse control disorders

Definition

Impulse control disorders are characterized by an individual's inability to resist the impulse to perform an action that is harmful to one's self or others. This condition is a relatively new class of **personality disorders**. Medical researchers surmise that at the root of the problem, the afflicted person desires small, short–term pleasures or gains—often performed impulsively and without the ability to resist such behaviors—over the likelihood of much larger, long–term losses. Some of the most common types of these disorders are **intermittent explosive disorder**, kleptomania, pyromania, compulsive **gambling disorder**, and trichotillomania.

Demographics

Such disorders are found in both genders of the population. They usually begin to appear in children in and around 7–15 years of age.

Description

All of these impulse control disorders involve the loss or lack of control in certain specific situations. The hallmark of these disorders is the individual's inability to stop impulses that may cause harm to themselves or others. Affected individuals often feel **anxiety** or tension in considering these behaviors. This anxiety or tension is relieved or diminished once the action is performed.

Intermittent explosive disorder (IED) is more common among males, and involves repeated and aggressive, violet outbursts that lead to assaults on others or destruction of property. These outbursts, often only 10–20 minutes in duration, are unprovoked or seem to be out of proportion to the event that precedes them. Afterwards, such people often feel remorse and regret from such actions. The outbursts may happen in several separate incidents over a few hours or days or may occur as one or more every so many weeks or months. Examples of intermittent explosive disorder commonly found in daily life include road rage, domestic violence and **abuse**.

Kleptomania is more common among females, and involves the theft of objects that are seemingly worthless. The act of stealing relieves tension and anxiety, and increases personal gratification during the act. Once the act is accomplished, individuals feel relieved of their tensions. In addition, they do not steal for the sense of monetary gain. The actual stealing is not preplanned, and the concept of punishment for the crime does not occur to these individuals, although they are aware that what they are doing is wrong. The people afflicted with kleptomania are often very ashamed of their actions afterwards, but are unable to stop themselves and oftentimes unwilling to seek medical or psychological help.

Pyromania is more common among males, and involves setting fires in order to feel pleasure and relieve tension. It is classified by the deliberate setting of fires more than once. Pyromaniacs do not start fires for the same reasons as do arsonists. They are not looking for revenge, monetary gain, or political reasons, only feelings of relief or gratification. They do not start fires as direct part of criminal behavior or due to **hallucinations** (such as with drug use). The individual exhibits a fascination and attraction to fire and any objects associated with it. Pryomanics often direct their actions toward fire stations and other buildings associated with fire control and prevention.

Pathological gambling occurs in roughly 1–3% of the population, and involves excessive (compulsive) gambling despite heavy monetary losses. This disorder typically begins in youth, and affected individuals are often competitive, easily bored, restless, and generous. Their losses actually act as a motivating factor in continuing gambling in order to recoup some of what was lost. Pathological gamblers often use lies, theft, and fraud to continue their compulsive gambling habit. They often gamble more during periods of high **stress** or anxiety in order to counter their feelings. Often, they gamble for the excitement and not for the money. However, many of them lose large amounts of money, which only makes them more anxious and, in turn, more likely to place larger and riskier bets.

Trichotillomania, also commonly called hair–pulling disorder, involves the uncontrollable, nearly continuous pulling of hair from one's own scalp, face, or other areas of the body, and is more common in females. It often begins in childhood, and is often associated with major depression or attention deficit/hyperactivity disorder. There is an increased sense of tension before pulling the hair, which is relieved once it is pulled out. Recurrent pulling out of one's hair may result in noticeable hair loss. It can be a mild problem for some people and in others, quite devastating. For all of them, the disorder is very emotional, especially when large amounts of hair are pulled from visible parts of the body, such as from the head. Affected individuals can undergo significant distress and impaired social, occupational, and functional behavior.

WWW.BOOKBAZ.IR

Causes and symptoms

The exact causes of impulse control disorders are not fully understood. Individuals who have had serious head injuries can be at a higher risk for developing impulse control disorders, as are those with **epilepsy**.

Some cases of impulse control disorders appear to be side effects of general medical conditions. Several groups of researchers have noted that some older adults with Parkinson's disease become compulsive gamblers as the disease progresses. It is thought that this gambling behavior is a side effect of dopaminergic drugs, as it does not respond to standard treatments for compulsive gambling but only to changes in the patient's medication. A study performed in 2007, headed by a medical researcher from the U.S. National Institute of Neurological Disorders and Stroke, found that pathological gamblers who received dopamine agonists developed Parkinson's disease at a younger age than those without the disorder. Those with the disorder also scored lower on an impulsivity scale than did other people.

Another medical condition associated with impulse control disorders is carcinoid syndrome. In one group of 20 patients with the syndrome, 75% met DSM diagnostic criteria for one or another impulse control disorder. The researchers attribute the connection to the high levels of serotonin (a neurotransmitter) produced by carcinoid tumors.

The cause of intermittent explosive disorder may be due to environmental, genetic, or biological factors, but the exact cause is still undetermined.

Numerous symptoms of intermittent explosive disorder are:

- irritability
- rage and anger
- tingling
- increased energy
- tremors and palpitations
- tightness of the chest
- headache or pressure in or about the head

The cause of kleptomania is not known for sure in the medical community. Some researchers have suggested that certain chemicals in the brain may be linked to the condition. However, additional research is needed before a determination of the cause of the disorder can be announced.

Some of the symptoms of kleptomania are:

- strong urges to steal even though the items are not needed
- tension and anxiety leading up to the act of stealing
- feelings of pleasure and satisfaction while in the act of the theft
- feelings of guilt, embarrassment, and shame afterwards

Although not known for sure, genetic and environmental factors are considered to be possible causes for pathological gambling. Certain natural occurring chemicals in the brain, such as dopamine, norepinephrine, and serotonin indicate possible associations with the disorder. Sometimes, medications taken (external to the disorder) may bring on the disorder. Serious injuries, such as brain **trauma**, can also contribute to pathological gambling.

Several symptoms of pathological gambling are:

- extreme excitement from taking large gambling bets
- being preoccupied with gambling
- increasing the number and/or amount of gambling bets
- showing more interest in gambling than other personal and professional interests
- lying about gambling
- feelings of remorse and guilt after gambling
- large debts and financial problems; also, some legal difficulties may develop
- problems holding onto job and career, and difficulties coping with family responsibilities

For trichotillomania, mutations in the gene SLITRK1 have been associated with the disorder. Tourette syndrome—in which people make unusual movements and sounds—is also linked to the disorder. Problems with natural chemicals in the brain, such as dopamine and serotonin, are suggested as a possible cause of trichotillomania.

Symptoms of trichotillomania include:

- bald or patchy spots on the scalp or other parts of the body
- excessive playing with hair or pulled–out hair, including chewing of hair
- thin or missing eyebrows and eyelashes
- pulling hair across the face, especially the lips

Diagnosis

A diagnosis of any of these impulse control disorders can be made only after other medical and psychiatric disorders that may cause the same symptoms have been ruled out. Once this is done a medical professional analyzes the physical and mental problems apparent to the patient.

In addition, many doctors administer questionnaires or similar psychiatric screeners as part of the differential diagnosis. Two instruments that were devised in the early 2000s to specifically target impulsive behavior are the Gambling Urge Scale (GUS) and the Lifetime History of Impulsive Behaviors (LHIB) Interview.

For instance, in a medical diagnosis of pathological gambling, five or more of the following symptoms must be present:

- a preoccupation with gambling
- a need to gamble with more money to achieve the thrill of winning
- repeated attempts to control or stop gambling
- irritability or restlessness due to repeated attempts of control
- gambling as an escape from stress
- lying to cover up gambling
- conducting illegal activities, such as embezzling or fraud, to finance gambling
- losing a job or personal relationship due to gambling
- borrowing money to fund gambling

KEY TERMS

Carcinoid syndrome—The pattern of symptoms (often including asthma and diarrhea) associated with carcinoid tumors of the digestive tract or lungs.

Compulsive gambling disorder—An impulse control disorder in which an individual cannot resist gambling despite repeated losses.

Intermittent explosive disorder—A personality disorder in which an individual is prone to intermittent explosive episodes of aggression during which he or she causes bodily harm or destroys property.

Kleptomania—An impulse control disorder in which one steals objects that are of little or no value.

Pyromania—An impulse control disorder in which one sets fires.

Trichotillomania—An impulse or compulsion to pull out one's own hair.

Treatment

A combination of psychological counseling and medication are the preferred treatments for impulse control disorders. For kleptomania, pyromania, and trichotillomania, behavior modification is usually the treatment of choice. Children with trichotillomania are often helped by antidepressant medication. For pathological gambling, treatment usually involves an adaptation of the model set forth by Alcoholics Anonymous. Individuals are counseled with the goal of eventually responding to appropriate social limits. In the case of intermittent explosive disorder, **anger management** and medication may be used in extreme cases of aggression.

Prognosis

These disorders can usually be controlled with medication, although the medication may need to be continued long–term to help prevent further aggressive outbursts. Long–term counseling is usually necessary as well. Support groups and meetings may also help these individuals.

The prognosis for intermittent explosive disorder, kleptomania, and pyromania is fair. Little is known about the prognosis for trichotillomania, and studies have shown that the condition can disappear for long periods (months to years) without any psychological counseling. For pathological gambling, the prognosis varies greatly from person to person. While total cure for this condition is unlikely, much like **alcoholism**, long periods of abstinence or continuous abstinence are possible.

Prevention

There are no known preventive treatments or measures for impulse control disorders.

In vitro fertilization

Definition

In vitro fertilization (IVF) is a procedure in which eggs (ova) from a woman's ovary are removed, they are fertilized with sperm in a laboratory procedure, and then the fertilized egg (embryo) is returned to the woman's uterus.

Purpose

IVF is one of several assisted reproductive techniques (ART) used to help infertile couples to conceive a child. If after one year of having sexual intercourse without the use of birth control a woman is unable to get pregnant, **infertility** is suspected. Some of the reasons for infertility are damaged or blocked fallopian tubes, hormonal imbalance, or **endometriosis** in the woman. In the man, low sperm count or poor quality sperm can cause infertility.

IVF is one of several possible methods to increase the chances for an infertile couple to become pregnant. Its use depends on the reason for infertility. IVF may be an option if there is a blockage in the fallopian tube or endometriosis in the woman, or low sperm count or poor quality sperm in the man. There are other possible treatments for these conditions, such as surgery for blocked tubes or endometriosis, which may be attempted before IVF.

IVF will not work for a woman who is incapable of ovulating or with a man who is not able to produce at least a few healthy sperm.

Demographics

IVF has been used successfully since 1978, when the first child to be conceived by this method was born in England. Over the past 30 years, thousands of couples have used this method of ART or similar procedures to conceive. More than five million babies around the world have been born using IVF. It is estimated that worldwide, 350,000 babies are born each year using IVF and this number is expected to continue to increase.

Description

IVF is a procedure in which the joining of egg and sperm takes place outside of a woman's body. A woman may be given fertility drugs before this procedure so that several eggs mature in the ovaries at the same time. The mature eggs (ova) are removed from the woman's ovaries using a long, thin needle. The physician has access to the ovaries using one of two possible procedures. One involves inserting the needle through the vagina (transvaginally); the physician guides the needle to the location in the ovaries with the help of an **ultrasound** machine. In the other procedure, called **laparoscopy**, a small thin tube with a viewing lens is inserted through an incision in the navel. This allows the physician to see on a video monitor inside the uterus to locate the ovaries.

Once the eggs are removed, they are mixed with sperm in a laboratory dish or test tube. (This is the origin of the term "test tube baby.") The eggs are monitored for several days. Once there is evidence that fertilization has occurred and the cells have begun to divide, they are then returned to the woman's uterus.

In the procedure to remove eggs, a sufficient number may be gathered to be frozen and saved (either fertilized or unfertilized) for additional IVF attempts.

Preparation

An obstetrician-gynecologist (OB-GYN) with specialized training in IVF supervises the activities of IVF. This specialist performs most of the procedures involving the woman. Most IVF activities are performed in a professional medical office.

Once a woman is determined to be a good candidate for IVF, she will generally be given fertility drugs to stimulate ovulation and the development of multiple eggs. These drugs may include gonadotropin-releasing hormone agonists (GnRHa), Pergonal, Clomid, or human chorionic gonadotropin (hCG). The maturation of the eggs is then monitored with ultrasound tests and frequent blood tests. If enough eggs mature, a physician will perform the procedure to remove them. The woman may be given a sedative prior to the procedure. A local anesthetic agent may also be used to reduce discomfort during the procedure.

The screening procedures and treatments for infertility can become a long, expensive, and, sometimes, disappointing process. Each IVF attempt takes at least an entire menstrual cycle and can cost $10,000–15,000, which may or may not be covered by health insurance, often depending on what state the couple reside in. The **anxiety** of dealing with infertility can challenge both individuals and their relationship. The added **stress** and expense of multiple clinic visits, testing, treatments, and surgical procedures can become overwhelming. Couples may want to receive counseling and support through the process.

Aftercare

After the IVF procedure is performed, the woman can resume normal activities. A **pregnancy** test can be done approximately 12–14 days after the procedure to determine if it was successful.

Risks

The risks associated with IVF include the possibility of a **multiple pregnancy** (since several embryos may be implanted) and **ectopic pregnancy** (an embryo that implants in the fallopian tube or in the abdominal cavity outside the uterus). There is a slight risk of ovarian rupture, bleeding, infections, and complications of **anesthesia**. In 2013, the first baby was born using a new IVF method, which decreases the risk of a woman developing the sometimes serious condition known as ovarian hyperstimulation syndrome. If IVF is successful and pregnancy is achieved, the pregnancy is believed by many to carry the same risks as any pregnancy achieved without assisted technology. However, research published in 2012 suggested that babies born using IVF are one-third more likely to have a birth defect than babies conceived naturally. This research is still ongoing, and for many couples, the opportunity to have a child outweighs the possible risks associated with IVF.

Results

Success rates vary widely among clinics and among physicians performing the procedure. The age of the woman also plays a major role in the success rate of IVF. Women under the age of 35 have a 30–35% chance of becoming pregnant each time the procedure is performed. This rate goes down as a woman's age increases. Women age 35–37 have a 25% chance of becoming pregnant, women age 38–40 have about a 15–20% chance, and women over 40 have only a 6–10% chance of becoming pregnant each time the procedure is performed. Therefore, the procedure may have to be repeated more than once to achieve pregnancy.

Abnormal results include an ectopic or multiple pregnancy that may abort spontaneously or that may require termination if the health of the mother is at risk.

Morbidity and mortality rates

The most common cause of morbidity is ectopic pregnancy. **Pain** is associated with most components of the procedure. Mortality as a result of IVF is extremely rare.

Alternatives

Other types of assisted reproductive technologies can be used to achieve pregnancy. A procedure called intracytoplasmic sperm injection (ICSI) utilizes a manipulation technique that must be performed using a microscope to inject a single sperm into each egg. The fertilized eggs can then be returned to the uterus, as in IVF. In gamete intrafallopian tube transfer (GIFT), the eggs and sperm are mixed in a narrow tube, and then deposited in the fallopian tube, where fertilization normally takes place. This accounts for about 2% of all ART procedures in the United States. Another variation on IVF is zygote intrafallopian tube transfer (ZIFT). As in IVF, the fertilization of the eggs occurs in a laboratory dish. And, similar to GIFT, the embryos are placed in the fallopian tube, rather than in the uterus as with IVF. ZIFT accounts for less than 1.5% of all ART procedures in the United States.

Inclusion blennorrhea *see* **Inclusion conjunctivitis**

Inclusion conjunctivitis

Definition

Inclusion **conjunctivitis** is an inflammation of the conjunctiva (the membrane that lines the eyelids and covers the white part, or sclera, of the eyeball) by the bacterium *Chlamydia trachomatis*. Chlamydia is a sexually transmitted organism. Chlamydia was originally called "chlamydozoa" by Polish dermatologist Ludwig Halberstaedter and Czech zoologist Stanislaus von Prowazek in 1907 when they discovered *Chlamydia trachomatis*. Chlamydozoa is the Greek word for "mantle."

Demographics

The disease usually affects teenagers and young adults who are sexually active. In fact, persons with the disease often times also have genital chlamydia (an infection of the genitals). The disease also occurs in newborn infants. Women are usually more susceptible to the disease than are men, and people in urban areas frequently acquire it more than do rural people.

Description

Inclusion conjunctivitis, known as neonatal inclusion conjunctivitis in the newborn and adult inclusion conjunctivitis in the adult, is also called inclusion blennorrhea, chlamydial conjunctivitis, or swimming pool conjunctivitis. It usually occurs from poor personal hygiene, specifically from the transmission of contaminated genital secretions to the eye. This disease affects four of 1,000 (0.4%) live births. Approximately half of the infants born to untreated infected mothers will develop the disease.

Causes and symptoms

Inclusion conjunctivitis in the newborn, called neonatal conjunctivitis, results from passage through an infected birth canal and develops 5–12 days after birth. Both eyelids and conjunctivae are swollen and red in color. There may be a discharge of pus from the eyes, swelling of the eyelids, and redness around the eye. Irritation, infection, or blocked tear ducts are three primary causes of inclusion conjunctivitis. In infants, the disease can become very serious.

KEY TERMS

Cervicitis—Inflammation of the cervix or neck of the uterus.

Conjunctiva—The membrane that lines the eyelids and covers the white part of the eyeball (sclera).

Cornea—The clear dome-shaped structure that covers the colored part of the eye (iris).

Neovascularization—Growth of new blood vessels.

Urethritis—Inflammation of the urethra, the canal for the discharge of urine that extends from the bladder to the outside of the body.

Most instances of adult inclusion conjunctivitis result from exposure to infected genital secretions. It is transmitted to the eye by fingers and occasionally by the water in swimming pools, poorly chlorinated hot tubs, or by sharing makeup. In adult inclusion conjunctivitis, one eye is usually involved, with a stringy discharge of mucus and pus. There may be little bumps called follicles inside the lower eyelid and the eye is red. Occasionally, the condition damages the cornea, causing cloudy areas and a growth of new blood vessels (neovascularization). Women sometimes report genito-urinary symptoms.

Diagnosis

Inclusion conjunctivitis is usually considered when the patient has a follicular conjunctivitis that will not go away, even after using **topical antibiotics**. Diagnosis depends upon tests performed on the discharge from the eye. Gram stains determine the type of microorganism, while culture and sensitivity tests determine which antibiotic will kill the harmful microorganism. Conjuntival scraping determines whether chlamydia is present in cells taken from the conjunctiva.

Treatment

Treatment in the newborn consists of administration of tetracycline ointment to the conjunctiva and erythromycin orally or through intravenous therapy for 14 days. Infants can also be given erythromycin ophthalmic ointment for one week, and erythromycin or azithromycin elixir for two to three weeks. The mother should be treated for **cervicitis** (inflammation of the uterine cervix) and the father for **urethritis** (inflammation of the urethra), even if they do not have symptoms of these diseases.

In adults, tetracycline ointment or drops should be applied to the conjunctiva and oral tetracycline, amoxacillin, or erythromycin should be taken for up to three weeks, or doxycycline for one week. A single oral dose of azithromycin helps to control redness in and around the eye, along with mucous discharge. In severe cases, intravenous **antibiotics** may also be used, together with topical antibiotics. If a blocked tear duct is to blame, warm and gentle massages are given between the nasal area and the eye. They help to reduce swelling and irritation. If the blocked tear duct does not heal within one year, surgery may be necessary.

Patients should have weekly checkups so the doctor can monitor the healing.

Oral tetracycline should not be administered to children whose permanent teeth have not erupted. It should also not be given to nursing or pregnant women.

Prognosis

Untreated inclusion conjunctivitis in the newborn persists for 3–12 months and usually heals; however, there may be scarring or neovascularization. The occurrence of it in infants has decreased over the past few decades as more women are screened and treated before they become pregnant. In the adult, if left untreated, the disease may continue for months and cause corneal neovascularization. Even if treated, antibiotics usually do not reverse damage that may have occurred, but they may help prevent it if given early enough. The infection can spread to the nasopharynx and the lower respiratory tract. **Pneumonia** can result if left untreated.

Prevention

The neonatal infection may be prevented by instilling erythromycin drops or ointment into the eye's conjunctival cul-de-sac at the baby's birth. Many state laws require medical professionals perform such preventative measures to babies born in hospitals. However, it is not prevented by silver nitrate, which was a treatment in the past. Instead, antibiotic eye drops are used.

Chlamydia is a contagious, sexually transmitted disease. Some systemic symptoms include a history of **vaginitis**, **pelvic inflammatory disease**, or urethritis. Patients with symptoms of these diseases should be treated by a physician.

Lorraine Steefel, RN

Incompetent cervix

Definition

A cervix (the structure at the bottom of the uterus) that is incompetent is abnormally weak, and can gradually widen during **pregnancy**. Left untreated, this can result in repeated pregnancy losses or premature delivery.

Description

Incompetent cervix is the result of an anatomical abnormality. Normally, the cervix remains closed throughout pregnancy until labor begins. An incompetent cervix gradually opens due to the pressure from the developing fetus after about the thirteenth week of pregnancy. The cervix begins to thin out and widen without any contractions or labor. The membranes surrounding the fetus bulge down into the opening of the cervix until they break, resulting in the loss of the baby or a very premature delivery.

Causes and symptoms

Some factors that can contribute to the chance of a woman having an incompetent cervix include **trauma** to the cervix, physical abnormality of the cervix, or having been exposed to the drug diethylstilbestrol (DES) in the mother's womb. Some women have cervical incompetence for no obvious reason.

Diagnosis

Incompetent cervix is suspected when a woman has three consecutive spontaneous pregnancy losses during the second trimester (the fourth, fifth and sixth months of the pregnancy). The likelihood of this happening by random chance is less than 1%. Spontaneous losses due to incompetent cervix account for 20–25% of all second trimester losses. A spontaneous second trimester pregnancy loss is different from a **miscarriage**, which usually happens during the first three months of pregnancy.

The physician can check for abnormalities in the cervix by performing a manual examination or by an **ultrasound** test. The physician can also check to see if the cervix is prematurely widened (dilated). Because incompetent cervix is only one of several potential causes for this, the patient's past history of pregnancy losses must also be considered when making the diagnosis.

Treatment

Treatment for incompetent cervix is a surgical procedure called cervical cerclage. A stitch (suture) is used to tie the cervix shut to give it more support. It is most effective if it is performed somewhere between 14–16 weeks into the pregnancy. The stitch is removed near the end of pregnancy to allow for a normal birth.

Cervical cerclage can be performed under spinal, epidural, or general **anesthesia**. The patient will need to stay in the hospital for one or more days. The procedure to remove the suture is done without the need for anesthesia. The vagina is held open with an instrument called a speculum and the stitch is cut and removed. This may be slightly uncomfortable, but should not be painful.

Some possible risks of cerclage are premature rupture of the amniotic membranes, infection of the amniotic sac, and preterm labor. The risk of infection of the amniotic sac increases as the pregnancy progresses. For a cervix that is dilated 1 in. (3 cm), the risk is 30%.

After cerclage, a woman will be monitored for any preterm labor. The woman needs to consult her obstetrician immediately if there are any signs of contractions.

KEY TERMS

Diethylstilbestrol (DES)—A drug given to women a generation ago to prevent miscarriage. At that time it was not known that female children born of women who had been given DES would show a higher rate for cervical and other reproductive abnormalities, as well as a rare form of vaginal cancer, when they reached reproductive age.

Effacement—The thinning out of the cervix that normally occurs along with dilation shortly before delivery.

Preterm labor—Labor before the thirty-seventh week of pregnancy.

Cervical cerclage can not be performed if a woman is more than 1.5 in. (4 cm) dilated, if the fetus has already died in her uterus, or if her amniotic membranes are torn and her water has broken.

Prognosis

The success rate for cerclage correction of incompetent cervix is good. About 80-90% of the time women deliver healthy infants. The success rate is higher for cerclage done early in pregnancy.

Incontinence *see* **Urinary incontinence**

Indigestion

Definition

Indigestion, which is sometimes called **dyspepsia** or an upset stomach, is a general term covering a group of nonspecific symptoms in the digestive tract. It is not considered a disease but, rather, several symptoms that are experienced due to impaired digestion of consumed foods. Indigestion is often described as an uncomfortable feeling of fullness, bloating, nausea, **heartburn**, or gassy discomfort in the chest or upper abdomen. The symptoms develop during meals or shortly afterward. In most cases, indigestion is a minor problem that often clears up without professional treatment.

Demographics

Indigestion is a widespread condition that can occur at any age, for both men and women. It is estimated to occur at some time in 25% of the adult population of the United States.

Description

Most people with indigestion do not feel sick enough to see a doctor; nonetheless, it is a common reason for office visits. About 3% of visits to primary care doctors are for indigestion. Indigestion may only occur occasionally in some people, while others may have it daily.

Causes and symptoms

Physical causes

The symptoms associated with indigestion have a variety of possible physical and lifestyle causes, ranging from commonplace food items to serious systemic disorders:

- Diet. Milk, milk products, alcoholic beverages, tea, and coffee cause indigestion in some people because they stimulate the stomach's production of acid. Chocolate, carbonated beverages, and spicy foods can also cause indigestion.
- Medications. Certain prescription drugs as well as over-the-counter medications can irritate the stomach lining. These medications include aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), some antibiotics, digoxin, theophylline, corticosteroids, iron (ferrous sulfate), oral contraceptives, and tricyclic antidepressants.
- Disorder of the stomach. Inflammation of the stomach (gastritis).
- Disorders of the pancreas and gallbladder. These include inflammation of the gallbladder or pancreas, cancer of the pancreas, and gallstones.
- Intestinal parasites. Parasitic infections that cause indigestion include amebiasis, fluke and tapeworm infections, giardiasis, and strongyloidiasis.
- Systemic disorders, including diabetes, thyroid disease, collagen vascular disease.

WWW.BOOKBAZ.IR

- Cancers of the digestive tract, such as stomach cancer.
- Conditions associated with women's reproductive organs. These conditions include menstrual cramps, pregnancy, and pelvic inflammatory disease.

Psychological and emotional causes

Indigestion often accompanies an emotional upset, because the part of the nervous system involved in the so-called "fight-or-flight" response also affects the digestive tract. People diagnosed with **anxiety**, nervousness, or **somatoform disorders** frequently have problems with indigestion. Many people in the general population, however, will also experience heartburn, "butterflies in the stomach," or stomach cramps when they are in upsetting situations—such as school examinations, arguments with family members, crises in their workplace, and other such emotional traumas. Some people's digestive systems appear to react more intensely to emotional **stress** due to hypersensitive nerve endings in their intestinal tract.

Symptoms

The most common symptoms include:

- Uncomfortable fullness in the stomach during and/or after meals, which lasts longer then normal, especially when not eating much food
- Awareness, mild discomfort, or even more severe pain, in the upper abdominal area, what is called the epigastric area
- Burning sensation in the upper abdomen (epigastric area)

Less common symptoms are:

- Bloating, with an uncomfortable feeling of tightness in the stomach
- Nausea, with a feeling that vomiting may occur
- Belching or burping

Specific gastrointestinal disorders

In some cases, the patient's description of the symptoms suggests a specific digestive disorder as the cause of the indigestion. Some doctors classify these cases into three groups.

ESOPHAGITIS TYPE. Esophagitis is an inflammation of the tube that carries food from the throat to the stomach (the esophagus). The tissues of the esophagus can become irritated by the flow (reflux) of stomach acid backward into the lower part of the esophagus. If the patient describes the indigestion in terms of frequent or intense heartburn, the doctor will consider **gastroesophageal reflux disease** (GERD) as a possible cause. GERD is a common disorder in the general population, affecting about 30% of adults.

PEPTIC ULCER TYPE. Patients who smoke and are over 45 years of age are more likely to have indigestion of the peptic ulcer type. This group also includes people who find that their indigestion is relieved by taking **antacids** or eating a small amount of food at each meal. Patients in this category are often found to have *Helicobacter pylori* infections. *H. pylori* is a rod-shaped bacterium that lives in the tissues of the stomach and causes irritation of the mucous lining of the stomach walls. Most people with *H. pylori* infections do not develop chronic indigestion, but the organism appears to cause peptic ulcer disease (PUD) in a vulnerable segment of the population.

NONULCER TYPE. Most cases of chronic indigestion—as many as 65%—fall into this third category. Nonulcer dyspepsia is sometimes called functional dyspepsia because it appears to be related to abnormalities in the way that the stomach empties its contents into the intestine. In some people, the stomach empties either too slowly or too rapidly. In others, the stomach's muscular contractions are irregular and uncoordinated as it receives, digests, and moves foods into the small intestine. These disorders of stomach movement (motility) may be caused by hypersensitive nerve endings in the stomach tissues. Patients in this group are likely to be younger than 45 years and have a history of taking medications for anxiety or depression.

Diagnosis

Patient history

Because indigestion is a nonspecific set of symptoms, patients who feel sick enough to seek medical attention are likely to go to their primary care doctor. The history does not always point to an obvious diagnosis. The doctor can, however, use the process of history-taking to evaluate the patient's mood or emotional state in order to assess the possibility of a psychiatric disturbance. In addition, asking about the location, intensity, timing, and recurrence of the indigestion can help the doctor weigh the different diagnostic possibilities.

An important part of the history-taking is asking about symptoms that may indicate a serious illness. These warning symptoms include:

- Weight loss
- Persistent vomiting

- Difficulty or pain in swallowing
- Vomiting blood or passing blood in the stools
- Anemia

Imaging studies

If the doctor thinks that the indigestion should be investigated further, he or she will order an endoscopic examination of the stomach. An endoscope is a slender tube-shaped instrument that allows the doctor to look at the lining of the patient's stomach. If the patient has indigestion of the esophagitis type or nonulcer type, the stomach lining will appear normal. If the patient has PUD (peptic ulcer disease) the doctor will be able to see abnormal breaks or ulcerated areas in the tissue. He or she may also order **ultrasound** imaging of the abdomen, or a radionuclide scan to evaluate the motility of the stomach. Blood, breath, or stool tests may also be ordered to show if a bacterium is causing the problem. In addition, a biopsy may be required to analyze pieces of the affected tissue for damage.

Laboratory tests

BLOOD TESTS. If the patient is over 45 years of age, the doctor will have the patient's blood analyzed for a complete blood cell count, measurements of liver enzyme levels, electrolyte and serum **calcium** levels, and thyroid function.

TESTS FOR *HELICOBACTER PYLORI*. Doctors can now test patients for the presence of *H. pylori* without having to take a tissue sample from the stomach. One of these noninvasive tests is a blood test and the other is a breath test.

Treatment

Since most cases of indigestion are not caused by serious disorders, many doctors prefer to try medications and other treatment measures before ordering an **endoscopy**.

Diet and stress management

Many patients benefit from the doctor's reassurance that they do not have a serious or fatal disorder. Cutting out alcoholic beverages, drinks containing **caffeine**, and carbonated beverages often helps. Eliminating tobacco products is also helpful. The patient may also be asked to keep a record of food intake, daily schedule, and symptom severity. Food diaries sometimes reveal psychological or dietary factors that influence indigestion. Eating smaller but more frequent meals can also be beneficial, especially when eaten slowly.

Medications

Patients with the esophagitis type of indigestion are often treated with H_2 antagonists. H_2 antagonists are drugs that block the secretion of stomach acid. They include ranitidine (Zantac), cimetidine (Tagamet), nizatidine (Axid), and famotidine (Pepcid).

Antacid-type medicines, some found over-the-counter and others with a prescription, are commonly taken to reduce acid production in the stomach. Most of these include different combinations of magnesium, aluminum, and calcium. These medicines are usually found over-the-counter, and include Maalox, Rolaids, Tums, and Mylanta.

Some patients take **proton pump inhibitors** (PPIs). They are usually given to people who have both indigestion and GERD. PPIs, which also reduce stomach acid, include omeprazole (Prilosec), lansoprazole (Prevacid), and exomeprazole (Nexium).

Patients with motility disorders may be given prokinetic drugs. Prokinetic medications speed up the emptying of the stomach and increase intestinal motility. They include metoclopramide (Reglan) and cisapride (Propulsid). These drugs relieve symptoms in about 75% of patients.

Removal of H. pylori

It is not clear that patients with *H. pylori* infections who have not developed gastric **ulcers** need to have the bacterium removed. Some studies indicate, however, that these patients may benefit from antibiotic therapy.

Alternatives

HERBAL MEDICINES. Practitioners of Chinese traditional herbal medicine might recommend medicines derived from peony (*Paeonia lactiflora*), hibiscus (*Hibiscus sabdariffa*), or hare's ear (*Bupleurum chinense*) to treat indigestion. Western herbalists are likely to prescribe fennel (*Foeniculum vulgare*), lemon balm (*Melissa officinalis*), or peppermint (*Mentha piperita*) to relieve stomach cramps and heartburn.

HOMEOPATHY. Homeopaths tailor their remedies to the patient's overall personality profile as well as the specific symptoms. Depending on the patient's reaction to the indigestion and some of its likely causes, the homeopath might choose *Gelsemium* (*Gelsemium sempervirens*), *Carbo vegetalis*, *Nux vomica*, or *Pulsatilla* (*Pulsatilla nigricans*).

WWW.BOOKBAZ.IR

KEY TERMS

Dyspepsia—Another name for indigestion.

Endoscope—A slender tubular instrument used to examine the inside of the stomach.

Gastroesophageal reflux disease (GERD)—A disorder of the lower end of the esophagus, caused by stomach acid flowing backward into the esophagus and irritating the tissues.

H_2 antagonist—A type of drug that relieves indigestion by reducing the production of stomach acid.

Heartburn—A popular term for an uncomfortable burning sensation in the stomach and lower esophagus, sometimes caused by the reflux of small amounts of stomach acid.

Helicobacter pylori—A gram-negative rod-shaped bacterium that lives in the tissues of the stomach and causes inflammation of the stomach lining.

Motility—The movement or capacity for movement of an organism or body organ. Indigestion is sometimes caused by abnormal patterns in the motility of the stomach.

Peptic ulcer disease (PUD)—A stomach disorder marked by corrosion of the stomach lining due to the acid in the digestive juices.

Prokinetic—A drug that works to speed up the emptying of the stomach and the motility of the intestines.

Reflux—The backward flow of a body fluid or secretion. Indigestion is sometimes caused by the reflux of stomach acid into the esophagus.

Other treatments

Some alternative treatments are aimed at lowering the patient's stress level or changing attitudes and beliefs that contribute to indigestion. These therapies and practices include **Reiki**, **reflexology**, **hydrotherapy**, therapeutic massage, **yoga**, and **meditation**.

Prognosis

Most cases of mild indigestion do not need medical treatment. For patients who consult a doctor and are given an endoscopic examination, 5–15% are diagnosed with GERD and 15–25% with PUD. About 1% of patients who are endoscoped have **stomach cancer**. Most patients with functional dyspepsia do well on either H_2 antagonists or prokinetic drugs, depending on the cause of their indigestion.

Prevention

Indigestion can often be prevented by attention to one's diet, general stress level, and ways of managing stress. Specific preventive measures include:

- Stop smoking.
- Cutting down on or eliminating alcohol, tea, or coffee.
- Avoiding foods that are highly spiced or loaded with fat.
- Eating slowly and keeping mealtimes relaxed.
- Practicing yoga or meditation.
- Not taking aspirin or other medications on an empty stomach.
- Keeping one's weight within normal limits.

Indium scan of the body

Definition

A scanning procedure in which a patient's white blood cells are first labeled with the radioactive substance indium, and then the patient's body is scanned as a way of tracking the white blood cells at the site of possible infection.

Purpose

The procedure is used to detect inflammatory processes in the body such as infections. By labeling the leukocytes (white blood cells), radiologists or nuclear medicine specialists can then watch their migration toward an **abscess** or other infection.

Description

A nuclear medicine technologist withdraws about 50 mL of blood. White blood cells are collected, exposed to indium, and reinjected by IV back into the patient.

The scan is scheduled for between 18 and 24 hours after the white blood cells have been labelled with indium. (In some cases, more scanning may be scheduled 48 hours after labeling).

For the scan, the patient lies on a special scanning table, as either a single camera passing underneath the table or two cameras (one above the table and one underneath) are placed as close as possible to the body, slowly scanning the person's body.

The radiologist may need extra pictures, but these take only a few minutes each.

While the patient must remain perfectly still during the scan, there should be no discomfort.

Aftercare

After the scan, the patient should be able to continue with normal daily activities with no problems.

Risks

The only risk during this scanning procedure could be to a patient who is pregnant, as with any type of injectable radioactive substance. If the woman is pregnant, the radiologist must be notified; if the scan is cleared, the radiologist may use a lower dosage of indium.

Results

The scan should reveal no infection or pathology.

KEY TERMS

Indium—A silvery metallic element with some nonmetallic chemical properties used to label white blood cells prior to scanning.

Leukocyte—A white blood cell protects the body against infection and fight infection when it occurs. They are bigger than red blood cells.

Abnormal results

The scan will reveal details, such as location, about an infection in the patient's body.

Carol A. Turkington

Induction of labor

Definition

Induction of labor involves using artificial means to assist the mother in delivering her baby.

Purpose

Labor is brought on, or induced, when the **pregnancy** has extended significantly beyond the expected delivery date and the mother shows no signs of going into labor. Generally, if the unborn baby is more than two weeks past due, labor will be induced. In most cases, a mother delivers her baby between 38–42 weeks of pregnancy. This usually means that labor is induced if the pregnancy has lasted more than 42 weeks. Labor is also induced if the mother has diseases (**preeclampsia**, chronic **hypertension**), if there is an Rh blood incompatibility between the baby and the mother, or if the mother or baby has a medical problem that requires delivery of the baby (like a premature rupture of the membranes).

Description

The uterus is the hollow female organ that supports the development and nourishment of the unborn baby during pregnancy. Sometimes labor is induced by the rupturing the amniotic membrane to release amniotic fluid. This is an attempt to mimic the normal process of "breaking water" that occurs early in the normal birth process. This method is sometimes

WWW.BOOKBAZ.IR

KEY TERMS

Cesarean section—Delivery of a baby through an incision in the mother's abdomen instead of through the vagina; also called a C-section.

Preeclampsia—Hypertension (high blood pressure) experienced during pregnancy.

Rh blood incompatibility—A blood type problem between mother (who is Rh negative) and baby (who is Rh positive), making the immune system of the mother attack her unborn baby. During delivery of the first pregnancy, the mother's immune system becomes sensitive to the Rh positive blood of the baby. The mother's system may then attack later pregnancies and cause severe illness or death to those babies.

Vasoconstriction—Constriction of a blood vessel.

enough stimulation to induce contractions in the mother's uterus. If labor fails to start, drugs are used.

Most labor is induced by using the drug Pitocin, a synthetic form of oxytocin. Oxytocin is a natural hormone produced in the body by the pituitary gland. During normal labor, oxytocin causes contractions. When labor does not occur naturally, the doctor may give the mother Pitocin to start the contractions. Pitocin makes the uterus contract with strength and force almost immediately. This drug is given through a vein in a steady flow that allows the doctor to control the amount the mother is given.

Sometimes vaginal gels are used to induce labor. Normally, the baby will pass through the opening of the uterus (the cervix) into the birth canal during delivery. Because of this, the cervix softens and begins to enlarge (dilate) during the early part of labor to make room for the baby to pass through. The cervix will continue to dilate, and the contractions will eventually push the baby out of the mother's body. When labor needs to be induced, the cervix is often small, hard, and not ready for the process. The doctor may need to prepare or "ripen" the cervix to induce labor. The hormone prostaglandin in a gel form may be applied high in the vagina to soften and dilate the cervix, making the area ready for labor. This may be enough to stimulate contractions on its own. More often, prostaglandin gel is used in conjunction with Pitocin.

If all attempts to induce labor fail, a **cesarean section** is performed.

Risks

Once labor has been induced, the unborn baby is monitored to guard against a reduction in its oxygen supply, or hypoxia. The drugs used to induce labor cause vasoconstriction, which can decrease blood supply to the unborn baby. Throughout the process, the baby's heart rate is monitored by an electronic device placed on top of the mother's abdomen. The heart rate is one sign that the unborn baby is getting enough oxygen and remains healthy. Once the membranes are broken, prolonged labor may result in infection to either the newborn or the mother.

Results

Once labor is induced and the cervix has dilated, labor usually proceeds normally. When performed properly, induced labor is a safe procedure for both mother and baby.

John T. Lohr, PhD

Infant massage

Definition

Infant massage refers to **massage therapy** as specifically applied to infants. In most cases, oil or lotion is used as it would be on an adult subject by a trained and licensed massage therapist. Medical professionals caring for infants might also use massage techniques on infants born prematurely, on those with motor or gastrointestinal problems, or on those who have been exposed to cocaine in utero.

Description

Various techniques are used in infant massage, with the different strokes specific to a particular therapy. Special handling is used for treating a baby with gas and **colic**. Some of the strokes are known as "Indian milking," which is a gentle stroking of the child's legs; and the "twist and squeeze" **stroke**, a gentle squeeze of the muscles in the thigh and calf. The light "feather" strokes often employed in regular

Infant receiving a massage. *(Photo Researchers, Inc.)*

Swedish massage are applied at the end of a massage. The procedure is not unlike certain forms of adult massage, but with extra care taken for the fragility of the infant.

There are also specific Chinese techniques of pediatric massage, including massage of children with special needs. In China, these forms of massage can be given by medical professionals, but parents are often taught how to do the simpler forms for home treatment of their children.

Origins

The practice of massaging infants dates back to ancient times, particularly in Asian and Pacific Island cultures; that is, massage was a component of the baby's regular bath routine among the Maoris of New Zealand and the natives of the Hawaiian Islands. Touch in these cultures is considered healthful both physically and spiritually. Infant massage was also recommended by practitioners of Ayurveda in ancient India. It is likely that early humans practiced infant massage, as many other species of mammals, such as cats, dogs, horses, and monkeys lick or groom their young after birth to cleanse and stimulate them.

In the West, however, infant massage has received more attention in recent years in conjunction with the popularity of natural **childbirth** and midwife-assisted births. Dr. Frédéric Leboyer, a French physician who was one of the leaders of the natural childbirth movement, helped to popularize infant massage through his photojournalistic book on the Indian art of baby massage.

Infant massage was introduced formally into the United States in 1978 when Vimala Schneider McClure, a **yoga** practitioner who had served in an orphanage in Northern India, developed a training program for instructors at the request of childbirth educators. An early research study by R. Rice in 1976 had showed that premature babies who were massaged surged ahead in weight gain and neurological development over those who were not massaged. From McClure's training in India, her knowledge of Swedish massage and **reflexology**, along with her knowledge of yoga postures that she had already adapted for babies, she became the foremost authority on infant massage. In 1986 she founded the International Association of Infant Massage (IAIM), which has chapters in more than 50 countries around the world as of 2014. Another group, the International Institute of Infant Massage, has trained instructors in 40 countries.

Results

According to the IAIM, the benefits of infant massage include:

- relaxation
- relief from stress
- interaction with adults, including fathers as well as mothers
- stimulation of the nervous system
- improved digestion and elimination
- improved blood circulation and skin condition
- relief of teething pains
- stimulation of oxytocin secretion in the person giving the massage. The IAIM states, "[Oxytocin] is useful as a pain reliever and has a calming effect on the person."

The results of several studies showed that infant massage alleviates the **stress** that newborns experience as a result of the enormous change that birth brings about in their lives after the 6–9 months they have spent in the womb. Both premature infants and full-term babies need the relaxation that comes from massaging and moving their limbs and muscles. In infants with colic, massage provides the relief necessary to disperse gas, ease **muscle spasms**, tone the digestive system and help it work efficiently. Some techniques even help bring relief from **teething** and emotional stress. The stimulation an infant receives from massage can aid circulation, strengthen muscles, help digestion, and relieve **constipation**. The bonding that occurs with massage between a parent and child enhances the entire process of bonding that comes with contact through all of the senses, including touch, voice, and sight. It affords a physical experience of quality time between the parents

WWW.BOOKBAZ.IR

KEY TERMS

Ayurveda—The traditional medical system of India, considered a form of alternative medicine in Western countries.

Linoleic acid—An unsaturated omega-6 fatty acid found in many plant oils that humans need in their diet. Plant oils rich in linoleic acid are beneficial to the skin when used in massage.

Oxytocin—A hormone secreted in the brains of mammals that acts as a neurotransmitter in the brain and also functions in sexual arousal, maternal behavior, and emotional bonding in humans. Synthetic oxytocin is used to induce or support labor in difficult childbirths.

and the child as well as with any significant others in a baby's life.

Precautions

Extreme caution is necessary when performing infant massage. Strokes are made with the greatest delicacy in order not to harm the infant in any way. Proper techniques are taught by licensed massage therapists or IAIM instructors, ensuring that the infant is treated with appropriate physical touch. Anyone who is unfamiliar with handling a baby should receive appropriate instruction before beginning infant massage.

Practitioners of infant massage advise the use of sunflower seed oil or other oils rich in linoleic acid for infant massage, and avoid the use of mustard oil. Mustard oil is used in some traditional societies for infant massage but can harm the baby's skin.

Preparation

If lotions or oils are used, care is taken to ensure their safety on a baby's delicate skin. The most important consideration is to use vegetable oils rather than mineral oils, which can clog the pores in the skin. The oil that is used should be warmed in the caregiver's hands before applying it to the baby's skin. The environment in which the massage is given to an infant should be comfortably warm, and as calm and nonthreatening as possible.

Aftercare

No specific aftercare is required after infant massage.

Risks

No adverse side effects have been reported when infant massage is done properly after careful instruction, or by a licensed massage therapist who specializes in infant care.

Research and general acceptance

In addition to the study already noted regarding touch therapy, a website devoted to infant massage lists research published as early as 1969, and cites hundreds of individual projects that have been conducted throughout the world focusing on infant massage. Many of the studies are related to the benefits of massage and touch for premature infants and others born with such risk factors as drug dependence. Conclusions regarding the benefits are overwhelmingly positive. The proliferation of therapists licensed in infant massage across the United States and worldwide indicates that infant massage is increasingly recognized as a legitimate healthcare treatment. According to the International Institute of Infant Massage, instructors in the field "include OTs and PTs, child-life specialists, nurses, developmental specialists, childbirth educators, social workers, early interventionists, speech pathologists, case workers, doctors, massage therapists, midwives, **lactation** consultants, and of course parents."

As of 2014, there were 22 research studies of infant massage registered with the National Institutes of Health (NIH). The studies are investigating the benefits of massage for preterm infants, including weight gain, strengthening of the immune system, and development of the central nervous system; sensitivity training for parents; the use of **aromatherapy** together with massage in relieving distress in infants; and the role of infant massage in preventing mother/infant relational disturbances.

Training and certification

The IAIM offers four-day workshops in the countries where it has chapters for the training and certification of instructors in infant massage. Certified instructors (CIMIs) receive their certification after completing "practice teachings with families," passing an examination at the end of the workshop, and passing a clinical evaluation by a registered IAIM trainer. The International Institute of Infant Massage offers a similar four-day program "which includes participation in the four-day training and successful completion of a peer review take-home exam, which includes a practicum of teaching five families during the following four-month period."

The licensing of massage therapists varies from state to state, as infant massage qualifies for consideration as

medical treatment. Infant massage is becoming an increasingly popular discipline within the field. Numerous websites provide listings for infant massage specialists throughout the United States. The IAIM course is recognized as the official course for infant massage, while the National Certification Board for Therapeutic Massage and Bodywork (NTCTMB) has approved the International Institute of Infant Massage as an approved provider of continuing education. Completion of the institute's course in infant massage is credited as 30 hours of continuing education.

Infection control

Definition

Infection control refers to policies and procedures used to minimize the risk of spreading infections, especially in hospitals and human or animal healthcare facilities.

WWW.BOOKBAZ.IR

Selected infectious diseases and corresponding treatment

Disease	Symptoms	Transmittal	Treatment
Chicken pox	Rash, low-grade fever	Person to person	None; acetaminophen may treat fever or discomfort
Common cold/influenza	Runny nose, sore throat, cough, fever, headache, muscle aches	Person to person	None, although various remedies may help relieve symptoms
Hepatitis A	Jaundice, flu-like symptoms	Sexual contact with an infected person or contact with contaminated blood, food, or water	None; acetaminophen may treat fever or pain
H1N1 influenza	Fever, cough, sore throat, body aches, loss of appetite, fatigue	Person to person	Antiviral drugs
Measles	Skin rash, runny nose and eyes, fever, cough	Person to person	None; acetaminophen may treat fever or discomfort
Meningitis	Neck pain, headache, pain caused by exposure to light, fever, nausea, drowsiness	Person to person	Antibiotics for bacterial meningitis, hospital care for viral meningitis
Methicillin-resistant Staphylococcus aureus (MRSA)	Rash, shortness of breath, fever, chest pain, headache	Person to person or contact with contaminated surfaces	Antibiotics
Mumps	Swelling of salivary glands	Person to person	Anti-inflammatory drugs
Ringworm	Skin rash	Contact with infected animal or person	Antifungal drugs applied topically or taken orally
Tetanus	Lockjaw, other spasms	Soil infection of wounds	Antibiotics, antitoxins, muscle relaxants

(Table by PreMediaGlobal. © Cengage Learning®.)

Purpose

The purpose of infection control is to reduce the occurrence of infectious diseases. These diseases are usually caused by bacteria or viruses and can be spread by human to human contact, animal to human contact, human contact with an infected surface, airborne transmission through tiny droplets of infectious agents suspended in the air, and, finally, by such common vehicles as food or water. Diseases that are spread from animals to humans are known as zoonoses; animals that carry disease agents from one host to another are known as vectors.

Infection control in hospitals and other settings

Infections contracted in hospitals are also called nosocomial infections. They occur in approximately 5% of all hospital patients. These infections result in increased time spent in the hospital and, in some cases, death. There are many reasons nosocomial infections are common, one of which is that many hospital patients have a weakened immune system that makes them more susceptible to infections. This weakened immune system can be caused either by the patient's diseases or by treatments given to the patient. Second, many medical procedures can increase the risk of infection by introducing infectious agents into the patient. Thirdly, many patients are admitted to hospitals because of **infectious disease**. These infectious agents can then be transferred from patient to patient by hospital workers or visitors.

Infection control has become a formal discipline in the United States since the 1950s, due to the spread of **staphylococcal infections** in hospitals. Because there is both the risk of healthcare providers acquiring infections themselves, and of their passing infections on to patients, the Centers for Disease Control and Prevention (CDC) established guidelines for infection control procedures. In addition to hospitals, infection control is important in nursing homes, clinics, child care centers, and restaurants, as well as in the home.

To lower the risk of nosocomial infections, the CDC began a national program of hospital inspection in 1970 known as the National Nosocomial Infections Surveillance system, or NNIS. The CDC reported that over 300 hospitals participate in the NNIS system as of the early 2000s. Data collected from the participating hospitals show that infection control programs can siginificantly improve patient safety, lower infection rates, and lower patient mortality.

ELIZABETH LEE HAZEN (1885–1975)

Elizabeth Lee Hazen was born on August 24, 1885, in Rich, Mississippi. Hazen, born the middle of three children to Maggie (Harper) and William Edgar Hazen, was orphaned before she turned four. She and her sister went to live with their aunt and uncle shorly after her younger brother died. Hazen attended the Mississippi Industrial Institute and College at Columbus, receiving her B.S. degree in 1910. During college, Hazen became interested in science and she studied biology at Columbia University, earning her M.S. in 1917. After working in the U.S. Army laboratories during World War I, she returned to Columbia where she received her Ph.D. in microbiology in 1927. Following her work as an instructor at Columbia, Hazen accepted a position with the New York Department of Health where she researched bacterial diseases.

In 1948, Hazen and Rachel Brown began researching fungal infections found in humans due to antibiotic treatments and diseases. Some of the antibiotics they discovered did indeed kill the fungus; however, they also killed the test mice. Finally, Hazen located a microorganism on a farm in Virginia, and Brown's tests indicated that the microorganism produced two antibiotics, one of which proved effective for treating fungus and candidiasis in humans. Brown purified the antibiotic which was patented under the name *nystatin*. In 1954, the antibiotic became available in pill form. Hazen and Brown continued their research and discovered two other antibiotics. Hazen received numerous awards individually and with her research partner, Rachel Brown. Elizabeth Hazen died on June 24, 1975.

Dental healthcare settings are similar to hospitals in that both personnel and equipment can transmit infection if proper safeguards are not observed. The CDC issued new guidelines in 2003 for the proper maintenance and sterilization of dental equipment, hand hygiene for dentists and dental hygienists, dental **radiology**, medications, and oral surgery, environmental infection control, and standards for dental laboratories.

The newest addition to the infection control specialist's resources is molecular typing, which speeds up the identification of a disease agent. Rapid identification in turn allows for timely containment of a disease outbreak.

Threat of emerging infectious diseases

Due to constant changes in our lifestyles and environments, new diseases are constantly appearing that people are susceptible to, making protection from the threat of infectious disease urgent. Many new contagious diseases have been identified in the past 30 years, such as **AIDS**, **Ebola**, and hantavirus. Increased travel between continents makes the worldwide spread of disease a bigger concern than it once was. Additionally, many common infectious diseases have become resistant to known treatments.

The emergence of the **severe acute respiratory syndrome (SARS)** epidemic in Asia in February 2003 was a classic instance of an emerging disease that spread rapidly because of the increased frequency of international and intercontinental travel. In addition, the **SARS** outbreak demonstrated the vulnerability of hospitals and healthcare workers to **emerging diseases**. Clusters of cases within hospitals occurred in the early weeks of the epidemic when the disease had not yet been recognized and the first SARS patients were admitted without **isolation** precautions.

The SARS epidemic also raised a number of ethical and legal questions regarding current attitudes toward infection control.

Problems of antibiotic resistance

Because of the overuse of **antibiotics**, many bacteria have developed a resistance to common antibiotics. This means that newer antibiotics must continually be developed in order to treat an infection. However, further resistance seems to come about almost simultaneously. This indicates to many scientists that it might become more and more difficult to treat infectious diseases. The use of antibiotics outside of medicine also contributes to increased **antibiotic resistance**. One example of this is the use of antibiotics in animal husbandry. These negative trends can only be reversed by establishing a more rational use of antibiotics through treatment guidelines.

Bioterrorism

The events of September 11, 2001, and the **anthrax** scare that followed in October 2001 alerted **public health** officials as well as the general public to the possible use of infectious disease agents as weapons of terrorism. The CDC now has a list of topics and resources related to bioterrorism on its web site.

Description

The goals of infection control programs are: immunizing against preventable diseases, defining precautions

WWW.BOOKBAZ.IR

KEY TERMS

Acquired immune deficiency syndrome (AIDS)—A disease that weakens the body's immune system. It is also known as HIV infection.

Antibiotic—A substance, such as a drug, that can stop a bacteria from growing or destroy the bacteria.

Antibiotic resistance—The ability of infectious agents to change their biochemistry in such a way as to make an antibiotic no longer effective.

Bioterrorism—The intentional use of disease-causing microbes or other biologic agents to intimidate or terrorize a civilian population for political or military reasons.

Ebola—The disease caused by the newly described and very deadly Ebola virus found in Africa.

Epidemiology—The branch of medicine that deals with the transmission of infectious diseases in large populations and with detection of the sources and causes of epidemics.

Hantavirus—A group of arboviruses that cause hemorrhagic fever (characterized by sudden onset, fever, aching and bleeding in the internal organs).

Immunization—Immunity refers to the body's ability to protect itself from a certain disease after it has been exposed to that disease. Through immunization, also known as vaccination, a small amount of an infectious agent is injected into the body to stimulate the body to develop immunity.

Immunocompromized—Refers to the condition of having a weakened immune system. This can happen due to genetic factors, drugs, or disease.

Nosocomial infection—An infection acquired in a hospital setting.

Staphylococcal infection—An infection caused by the organism *Staphlococcus*. Infection by this agent is common and is often resistant to antibiotics.

Vector—An animal carrier that transfers an infectious organism from one host to another.

Zoonosis (plural, zoonoses)—Any disease of animals that can be transmitted to humans under natural conditions. Lyme disease, rabies, psittacosis (parrot fever), cat-scratch fever, and monkeypox are examples of zoonoses.

that can prevent exposure to infectious agents, and restricting the exposure of healthcare workers to an infectious agent. An infection control practitioner is a specially trained professional, oftentimes a nurse, who oversees infection control programs.

Commonly recommended precautions to avoid and control the spread of infections include:

- Vaccinate people and pets against diseases for which a vaccine is available. The vaccines used against infectious diseases are very safe compared to most drugs.
- Wash hands often.
- Cook food thoroughly.
- Use antibiotics only as directed.
- See a doctor for infections that do not heal.
- Avoid areas with a lot of insects.
- Be cautious around wild or unfamiliar animals, or any animals that are unusually aggressive. Do not purchase exotic animals as pets.
- Do not engage in unprotected sex or in intravenous drug use.
- Find out about infectious diseases when you make travel plans. Travelers' advisories and adult vaccination recommendations are available on the CDC web site or by calling them directly.

Because of the higher risk of spreading infectious disease in a hospital setting, higher levels of precautions are taken there. Typically, healthcare workers wear gloves with all patients, since it is difficult to know whether a transmittable disease is present or not. Patients who have a known infectious disease are isolated to decrease the risk of transmitting the infectious agent to another person. Hospital workers who come in contact with infected patients must wear gloves and gowns to decrease the risk of carrying the infectious agent to other patients. All articles of equipment that are used in an isolation room are decontaminated before reuse. Patients who are immunocompromised may be put in protective isolation to decrease the risk of infectious agents being brought into their room. Any hospital worker with infections, including colds, are restricted from that room.

Hospital infections can also be transmitted through the air. Care must be taken when handling infected materials so as to decrease the numbers of infectious agents that become airborne. Special care should also be taken with hospital ventilation systems to prevent recirculation of contaminated air.

Infectious arthritis

Definition

Infectious arthritis, which is sometimes called septic arthritis or pyogenic arthritis, is a serious infection of the joints characterized by **pain**, **fever**, occasional chills, inflammation and swelling in one or more joints, and loss of function in the affected joints. It is considered a medical emergency.

Description

Infectious arthritis can occur in any age group, including newborns and children. In adults, it usually affects the wrists or one of the patient's weight-bearing joints—most often the knee—although about 20% of adult patients have symptoms in more than one joint. Multiple joint infection is common in children and typically involves the shoulders, knees, and hips.

Some groups of patients are at greater risk for developing infectious arthritis. These high-risk groups include:

- Patients with chronic rheumatoid arthritis.
- Patients with certain systemic infections, including gonorrhea and HIV infection. Women and male homosexuals are at greater risk for gonorrheal arthritis than are male heterosexuals.

WWW.BOOKBAZ.IR

- Patients with certain types of cancer.
- IV drug abusers and alcoholics.
- Patients with artificial (prosthetic) joints.
- Patients with diabetes, sickle cell anemia, or systemic lupus erythematosus (SLE).
- Patients with recent joint injuries or surgery, or patients receiving medications injected directly into a joint.

Causes and symptoms

In general, infectious arthritis is caused by the spread of a bacterial, viral, or fungal infection through the bloodstream to the joint. The disease agents may enter the joint directly from the outside as a result of an injury or a surgical procedure, or they may be carried to the joint by the blood from infections elsewhere in the body. The specific organisms vary somewhat according to age group. Newborns are most likely to acquire gonococcal infections of the joints from a mother with **gonorrhea**. Children may also acquire infectious arthritis from a hospital environment, often as a result of catheter placement. The organisms involved are usually either *Haemophilus influenzae* (in children under two years of age) or *Staphylococcus aureus*. In older children or adults, the infectious organisms include *Streptococcus pyogenes* and *Streptococcus viridans* as well as *S. aureus*. *Staphylococcus epidermidis* is usually involved in joint infections related to surgery. Sexually active teenagers and adults frequently develop infectious arthritis from *Neisseria gonorrhoeae* infections. Older adults are often vulnerable to joint infections caused by gram-negative bacilli, including *Salmonella* and *Pseudomonas*.

Infectious arthritis often has a sudden onset, but symptoms sometimes develop over a period of 3–14 days. The symptoms include swelling in the infected joint and pain when the joint is moved. Infectious arthritis in the hip may be experienced as pain in the groin area that becomes much worse if the patient tries to walk. In 90% of cases, there is some leakage of tissue fluid into the affected joint. The joint is sore to the touch; it may or may not be warm to the touch, depending on how deep the infection lies within the joint. In most cases the patient will have fever and chills, although the fever may be only low-grade. Children sometimes develop **nausea and vomiting**.

Septic arthritis is considered a medical emergency because of the damage it causes to bone as well as cartilage, and its potential for creating **septic shock**, which is a potentially fatal condition. *S. aureus* is capable of destroying cartilage in one or two days. Destruction of cartilage and bone in turn leads to **dislocations** of the joints and bones. If the infection is caused by bacteria, it can spread to the blood and surrounding tissues, causing abscesses or even blood **poisoning**. The most common complication of infectious arthritis is **osteoarthritis**.

Diagnosis

The diagnosis of infectious arthritis depends on a combination of laboratory testing with careful history-taking and **physical examination** of the affected joint. It is important to keep in mind that infectious arthritis can coexist with other forms of arthritis, **gout**, **rheumatic fever**, **Lyme disease**, or other disorders that can cause a combination of joint pain and fever. In some cases, the doctor may consult a specialist in orthopedics or rheumatology to avoid misdiagnosis.

Patient history

The patient's history will tell the doctor whether he or she belongs to a high-risk group for infectious arthritis. Sudden onset of joint pain is also important information.

Physical examination

The doctor will examine the affected joint for swelling, soreness, warmth, and other signs of infection. Location is sometimes a clue to diagnosis; infection of an unusual joint, such as the joints between the breastbone and collarbone, or the pelvic joints, often occurs in drug abusers.

Laboratory tests

Laboratory testing is necessary to confirm the diagnosis of infectious arthritis. The doctor will perform an arthrocentesis, which is a procedure that involves withdrawing a sample of synovial fluid (SF) from the joint with a needle and syringe. SF is a lubricating fluid secreted by tissues surrounding the joints. Patients should be warned that arthrocentesis is a painful procedure. The fluid sample is sent for culture in the sealed syringe. SF from infected joints is usually streaked with pus or looks cloudy and watery. Cell counts usually indicate a high level of white cells; a level higher than 100,000 cells/mm^3 or a neutrophil proportion greater than 90% suggests septic arthritis. A Gram's stain of the culture obtained from the SF is usually positive for the specific disease organism.

KEY TERMS

Arthrocentesis—A procedure in which the doctor inserts a needle into the patient's joint to withdraw fluid for diagnostic testing or to drain infected fluid from the joint.

Pyogenic arthritis—Another name for infectious arthritis. Pyogenic means that pus is formed during the disease process.

Sepsis—Invasion of the body by disease organisms or their toxins. Generalized sepsis can lead to shock and eventual death.

Septic arthritis—Another name for infectious arthritis.

Synovial fluid (SF)—A fluid secreted by tissues surrounding the joints that lubricates the joints.

Doctors sometimes order a biopsy of the synovial tissue near the joint if the fluid sample is negative. Cultures of other body fluids, such as urine, blood, or cervical mucus, may be taken in addition to the SF culture.

Diagnostic imaging

Diagnostic imaging is not helpful in the early stages of infectious arthritis. Destruction of bone or cartilage does not appear on x rays until 10–14 days after the onset of symptoms. Imaging studies are sometimes useful if the infection is in a deep-seated joint.

Treatment

Infectious arthritis usually requires several days of treatment in a hospital, with follow-up medication and **physical therapy** lasting several weeks or months.

Medications

Because of the possibility of serious damage to the joint or other complications if treatment is delayed, the patient will be started on intravenous **antibiotics** before the specific organism is identified. After the disease organism has been identified, the doctor may give the patient a drug that targets the specific bacterium or virus. **Nonsteroidal anti-inflammatory drugs** are usually given for viral infections.

Intravenous antibiotics are given for about two weeks, or until the inflammation has disappeared. The patient may then be given a two- to four-week course of oral antibiotics.

Surgery

In some cases, surgery is necessary to drain fluid from the infected joint. Patients who need surgical drainage include those who have not responded to antibiotic treatment, those with infections of the hip or other joints that are difficult to reach with arthrocentesis, and those with joint infections related to gunshot or other penetrating **wounds**.

Patients with severe damage to bone or cartilage may need **reconstructive surgery**, but it cannot be performed until the infection is completely gone.

Monitoring and supportive treatment

Infectious arthritis requires careful monitoring while the patient is in the hospital. The doctor will drain the joint on a daily basis and remove a small sample of fluid for culture to check the patient's response to the antibiotic.

Infectious arthritis often causes intense pain. Patients are given medications to relieve pain, together with hot compresses or ice packs on the affected joint. In some cases the patient's arm or leg is put in a splint to protect the sore joint from accidental movement. Recovery can be sped up if the patient practices range-of-motion exercises to the extent that the pain allows.

Prognosis

The prognosis depends on prompt treatment with antibiotics and drainage of the infected joint. About 70% of patients will recover without permanent joint damage. However, many patients will develop osteoarthritis or deformed joints. Children with infected hip joints sometimes have damage to the growth plate. If treatment is delayed, infectious arthritis has a mortality rate between 5% and 30% due to septic **shock** and **respiratory failure**.

Prevention

Some cases of infectious arthritis are preventable by lifestyle choices. These include avoidance of self-injected drugs; sexual abstinence or monogamous relationships; and prompt testing and treatment for suspected cases of gonorrhea. Patients receiving corticosteroid injections into the joints for osteoarthritis may want to weigh this treatment method against the increased risk of infectious arthritis.

Infectious disease

Definition

Infectious disease—also called communicable disease—is any illness caused by an infective agent—a germ, microbe, or parasite. Infective agents include bacteria, viruses, fungi, parasitic protozoa, and worms.

Demographics

Virtually all children contract infectious disease, especially during infancy and early childhood. Respiratory and gastrointestinal infections are the most common causes of illness in children. For instance, children develop three to eight colds or respiratory infections per year.

Worldwide, more children and adults die from infectious disease than any other single cause. The vast majority of these deaths occur in poorer counties with limited access to prevention, medical care, and drugs.

Among American children, the frequency and severity of infectious disease have declined dramatically in recent decades, primarily due to the development of vaccines for common childhood infections. The United States is one of the few places in the world where **polio** has been completely eradicated. Childhood pneumococcal infections caused by vaccine–targeted bacterial strains have been almost completely eliminated.

Description

When an infective agent enters the body and begins to multiply, the immune system responds with various defensive mechanisms that protect against most infectious disease. However, when an infective

A teenager with measles. *(Sally and Richard Greenhill / Alamy.)*

agent temporarily evades or overwhelms the immune system and begins to damage tissues, signs and symptoms of disease develop.

The most common infectious diseases are contagious—they spread via direct transfer of an infective agent from one person to another. Shaking hands, kissing, or coughing or sneezing on someone can directly transmit contagious diseases such as colds, flu, or **tuberculosis** (TB). Some infective agents, including cold viruses, can be contracted by indirect contact with a contaminated surface such as a faucet, doorknob, or computer keyboard. International airplane travel is responsible for the spread of contagious diseases around the world. Infant **diarrhea** caused by rotavirus or the protozoan *Giardia lamblia* often spreads among babies and young children through the accidental transferring of feces from hand to mouth after diaper changes. Some infectious diseases can be passed from a mother to her unborn child across the placenta or during birth.

Other infectious diseases can be transmitted from animals or animal waste to humans. Dog and cat saliva may contain more than 100 different types of infective agents. *Pasteurella* bacteria are the most common microbes transmitted via pet bites. These bacteria can cause serious—sometimes fatal—infectious diseases such as **meningitis**, an inflammation of the lining of the brain and spinal cord. **Toxoplasmosis** is a bacterial infection that is transmitted via cat feces. Pet reptiles, such as turtles, snakes, and iguanas, can transmit *Salmonella* bacteria. Wild animals can directly or indirectly transmit a wide variety of infectious disease.

Some infectious diseases are transferred between human hosts by insect and other invertebrate vectors:

- Mosquitoes transfer the protozoan that causes malaria, as well as West Nile virus, dengue fever, and viral encephalitis.
- Body lice can transmit typhus.
- Fleas can transmit typhus and transfer plague bacteria from rodents to humans.
- Deer ticks—which are actually more closely related to crabs than to insects—can transfer the bacterium that causes Lyme disease from mice to humans.
- Ticks can also transmit the bacterium that cause Rocky Mountain spotted fever and tularemia, and the protozoan that causes babesiosis.

Diagnosis

Examination

A medical history and physical exam—including the patient's breathing pattern and respiratory rate, body temperature, and other symptoms—may be sufficient for diagnosing an infectious disease. Sometimes an infectious organism in a blood or urine sample can be seen under a microscope.

Tests

Blood, urine, throat swabs, or other bodily secretions may be cultured in a laboratory to identify the infective agent. Diagnosis of some infectious diseases requires a **lumbar puncture** or spinal tap to obtain a sample of cerebrospinal fluid.

Procedures

Diagnostic procedures may include:

- a chest x ray to diagnose pneumonia
- computerized tomography (CT) scans or magnetic resonance imaging (MRI)
- a biopsy—the removal of a tiny amount of tissue from an infected area, such as the lung, for diagnosing fungal pneumonia

Treatment

Treatment depends on the type of infectious disease. Some diseases resolve on their own without any treatment other than possibly relieving symptoms.

Drugs vary based on the infecting organism and specific disease:

- Bacterial infections are treated with antibiotics.
- A very few antiviral drugs, such as acyclovir, are available for treating viral infections such as flu and herpes.
- Various drugs may be used to treat hepatitis B and C.
- HIV/AIDS is treated with a combination of drugs, commonly known as highly active antiretroviral therapy (HAART).
- Fungal infections of the skin and nails may be treated with over–the–counter or prescription medications applied directly to the affected area.
- Oral antifungal medications are used to treat systemic fungal infections, such as histoplasmosis, or severe infections of the mouth and throat in children with weakened immune systems.
- Only a very few anti–parasitic drugs are available, and some of these are either very toxic or are becoming less effective with the spread of drug–resistant parasites.

A wide variety of home or alternative therapies are also used to treat infectious disease, although bacterial infections usually require **antibiotics**. Yogurt containing healthy gut bacteria can ease gastrointestinal symptoms and has been shown to reduce the incidence of some common infections in children. Many mild infectious

WWW.BOOKBAZ.IR

diseases respond well to home remedies. Bed rest and drinking plenty of fluids are the most common remedies.

Prognosis

Prognosis varies greatly, depending on the type of infectious disease. Some, such as the **common cold**, usually resolve quickly without medical treatment, and most infectious diseases have only minor complications. Some—such as **pneumonia** or meningitis—can be life-threatening. Even some common and usually mild infectious diseases—such as **measles**, **mumps**, chicken pox, or seasonal flu—can be dangerous or life–threatening in very young children.

Prevention

Many common infectious diseases are preventable with good hygiene and vaccines. The best protection is frequent and thorough hand washing:

- before, during, and after handling food
- before eating
- after using the toilet
- after changing diapers
- after touching animals or their toys, leashes, or waste
- after touching trash, cleaning rags, drains, or soil
- after contact with body fluids, including blood, vomit, saliva, or nasal secretions
- before cleaning a wound, administering medicine, or inserting contact lenses
- more often, if someone in the home is ill

Hands should be washed thoroughly and vigorously with soap and water for 20 seconds. If soap and water are not available, alcohol–based disposable hand wipes or sanitizers are an alternative.

Other practices for preventing infectious disease include:

- breastfeeding infants, which helps protect babies from respiratory and gastrointestinal infections
- avoiding touching one's eyes, nose, and mouth
- covering one's mouth and nose when coughing or sneezing
- rinsing fresh fruit and vegetables under running water and scrubbing firm–skinned produce with a vegetable brush
- keeping meat, poultry, seafood, and eggs separated from other foods at all times
- refrigerating foods promptly at a constant temperature of 40°F (4°C) or below, with enough room for cold air to circulate freely
- freezing foods at 0°F (–18°C) or below
- using separate cutting boards for produce and meat, poultry, seafood, or eggs
- washing cutting boards, dishes, utensils, and counter tops with hot, soapy water between preparation of each food item
- never reusing marinades from raw foods without boiling first
- thoroughly cooking all foods, especially meat, at the correct temperature
- cleaning with disposable paper towels or wipes, cloth towels that are washed in hot water, or sponges that are washed in the dishwasher or microwaved daily for 30 seconds
- cleaning and disinfecting all bathroom surfaces, especially when someone in the home has an infectious disease
- avoiding sharing personal items, including toothbrushes, combs, drinking glasses, and eating utensils
- keeping children home when they are sick
- not flying when ill
- practicing safe sex or abstaining from sex entirely to avoid sexually transmitted infections that can be passed to unborn children

Precautions against contracting infectious disease from animals include:

- adopting pets from an animal shelter or purchasing from a reputable store or breeder
- obtaining routine care and immunizations for your pet from a veterinarian
- obeying leash laws
- cleaning litter boxes daily, except when a person is pregnant
- keeping children away from pet waste
- keeping sandboxes covered
- washing one's hands thoroughly after contact with animals
- keeping wild animals away from the house
- using insect repellent and routinely checking for ticks and removing them immediately by applying gentle, steady pressure with tweezers

Children should receive all recommended vaccinations on schedule. Adults should receive vaccinations and booster shots (such as **tetanus** booster shots) as necessary. Travelers should also consult a healthcare professional about recommended immunizations for travel.

Effects on Public Health

More than a quarter of the annual global death rate can be traced to infectious diseases. In developing

countries, the impact is even greater. As the world population grows, people move freely between geographic areas, and infectious agents evolve into virulent strains (some of which are difficult to treat), new and resurging infectious diseases will continue to emerge, and some will pose serious threats to **public health**. With international air travel, these diseases have the potential to reach epidemic levels in a matter of days.

COSTS TO SOCIETY. Infectious diseases can have devastating consequences. This is especially evident in developing countries, where infectious disease affects a higher proportion of the population. Sickness not only results in increased inpatient and outpatient healthcare costs, but also in indirect economic costs associated with lost productivity when individuals cannot work, are prevented from ever working, or die. Costs also mount when people must cut back on their own employment to care for an ailing family member.

Infectious disease can be particularly detrimental to the youngest members of society. According to a 2010 research article in *Lancet*, infectious disease in 2008 killed 5,970,000 children under the age of five, accounting for 68% of all deaths in that age group: an estimated 18% died of pneumonia, 15% of diarrhea, and 8% of malaria.

EFFORTS AND SOLUTIONS. Many efforts are under way to curb the health threats posed by infectious diseases. The task is great, but the global health community has made headway. For instance, thanks in great part to the Maternal and Neonatal Tetanus (MNT) Elimination Initiative of the World Health Organization (WHO), United Nations Children's Fund (UNICEF), and the United Nations Population Fund (UNFPA), the number of deaths due to neonatal tetanus has dropped from 787,000 in the late 1980s to 59,000 in 2008 (the latest data available). In 1979, **smallpox** was officially and completely eradicated. A vaccine for polio has eliminated the disease from most of the world.

Labs are developing new antimicrobials and other novel treatments; governments and agencies are reviewing and improving disease surveillance measures; researchers are studying how diseases spread and developing computer models to predict epidemics; molecular biologists are uncovering the genomes of disease organisms and identifying vulnerabilities; and health organizations are working on means to disseminate vaccines, both widely and rapidly.

Infectious mononucleosis

Definition

Infectious mononucleosis is a contagious illness caused by the **Epstein-Barr virus** that can affect the liver, lymph nodes, and oral cavity. While mononucleosis is not usually a serious disease, its primary symptoms of **fatigue** and lack of energy can linger for several months.

Description

Infectious mononucleosis, frequently called "mono" or the "kissing disease," is caused by the Epstein-Barr virus (EBV) found in saliva and mucus. The virus affects a type of white blood cell called the B lymphocyte producing characteristic atypical lymphocytes that may be useful in the diagnosis of the disease.

While anyone, even young children, can develop mononucleosis, it occurs most often in young adults between the ages of 15 and 35 and is especially common in teenagers. The mononucleosis infection rate among college students who have not previously been exposed to EBV has been estimated to be about 15%. In younger children, the illness may not be recognized.

The disease typically runs its course in four to six weeks in people with normally functioning immune systems. People with weakened or suppressed immune systems, such as **AIDS** patients or those who have had organ transplants, are particularly vulnerable to the potentially serious complications of infectious mononucleosis.

Sore throat and swollen tonsils caused by infectious mononucleosis. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

Causes and symptoms

The EBV that causes mononucleosis is related to a group of herpes viruses, including those that cause **cold sores**, chicken pox, and **shingles**. Most people are exposed to EBV at some point during their lives. Mononucleosis is most commonly spread by contact with virus-infected saliva through coughing, sneezing, kissing, or sharing drinking glasses or eating utensils.

In addition to general weakness and fatigue, symptoms of mononucleosis may include any or all of the following:

- Sore throat and/or swollen tonsils
- Fever and chills
- Nausea and vomiting, or decreased appetite
- Swollen lymph nodes in the neck and armpits
- Headaches or joint pain
- Enlarged spleen
- Jaundice
- Skin rash

Complications that can occur with mononucleosis include a temporarily enlarged spleen or inflamed liver. In rare instances, the spleen may rupture, producing sharp **pain** on the left side of the abdomen, a symptom that warrants immediate medical attention. Additional symptoms of a ruptured spleen include light headedness, rapidly beating heart, and difficulty breathing. Other rare, but potentially life-threatening, complications may involve the heart or brain. The infection may also cause significant destruction of the body's red blood cells or platelets.

Symptoms do not usually appear until four to seven weeks after exposure to EBV. An infected person can be contagious during this incubation time period and for as many as five months after the disappearance of symptoms. Also, the virus will be excreted in the saliva intermittently for the rest of their lives, although the individual will experience no symptoms. Contrary to popular belief, the EBV is not highly contagious. As a result, individuals living in a household or college dormitory with someone who has mononucleosis have a very small risk of being infected unless they have direct contact with the person's saliva.

Diagnosis

If symptoms associated with a cold persist longer than two weeks, mononucleosis is a possibility; however, a variety of other conditions can produce similar symptoms. If mononucleosis is suspected, a physician will typically conduct a **physical examination**, including a "Monospot" antibody blood test

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Herpes viruses—A group of viruses that can cause cold sores, shingles, chicken pox, and congenital abnormalities. The Epstein-Barr virus that causes mononucleosis belongs to this group of viruses.

Reye's syndrome—A very serious, rare disease, most common in children that involves an upper respiratory tract infection followed by brain and liver damage.

that can indicate the presence of proteins or antibodies produced in response to infection with EBV. These antibodies may not be detectable until the second or third weeks of the illness. Occasionally, when this test is inconclusive, other blood tests may be conducted.

Treatment

The most effective treatment for infectious mononucleosis is rest and a gradual return to regular activities. Individuals with mild cases may not require bed rest but should limit their activities. Any strenuous activity, athletic endeavors, or heavy lifting should be avoided until the symptoms completely subside, since excessive activity may cause the spleen to rupture.

The **sore throat** and **dehydration** that usually accompany mononucleosis may be relieved by drinking water and fruit juices. Gargling salt water or taking throat lozenges may also relieve discomfort. In addition, taking over-the-counter medications, such as **acetaminophen** or ibuprofen, may relieve symptoms, but **aspirin** should be avoided because mononucleosis has been associated with Reye's syndrome, a serious illness aggravated by aspirin.

While **antibiotics** do not affect EBV, the sore throat accompanying mononucleosis can be complicated by a streptococcal infection, which can be treated with antibiotics. Cortisone anti-inflammatory medications are also occasionally prescribed for the treatment of severely swollen tonsils or throat tissues.

Prognosis

While the severity and length of illness varies, most people diagnosed with mononucleosis will be able to return to their normal daily routines within two to three weeks, particularly if they rest during this time period. It may take two to three months before a person's usual energy levels return. One of the most common problems in treating mononucleosis, particularly in teenagers, is that people return to their usual activities too quickly and then experience a relapse of symptoms. Once the disease has completely run its course, the person cannot be reinfected.

Prevention

Although there is no way to avoid becoming infected with EBV, paying general attention to good hygiene and avoiding sharing beverage glasses or having close contact with people who have mononucleosis or cold symptoms can help prevent infection.

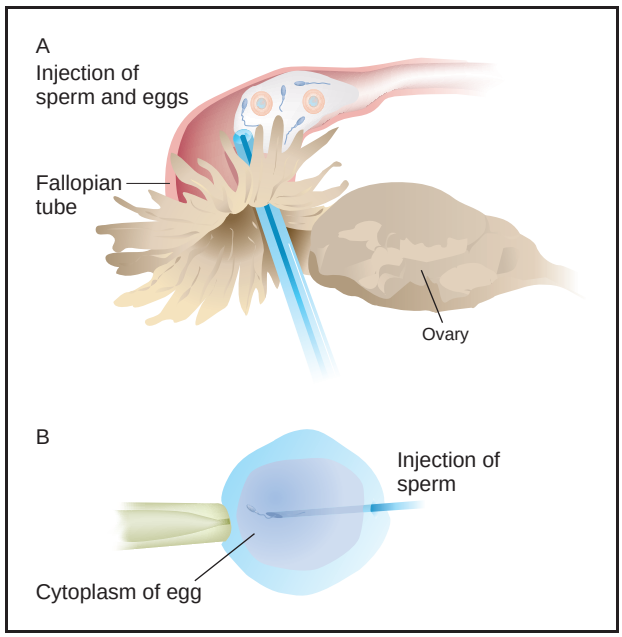
Susan J. Montgomery

Infertility

Definition

Infertility, is the biological failure of a couple to conceive a **pregnancy** after trying to do so frequently and without the use of contraceptives for at least one full year. In primary infertility, pregnancy has never occurred. In secondary infertility, one or both members of the couple has previously conceived, but is unable to conceive again after a full year of trying. The inability to conceive may be due to a single cause or multiple causes, in either the female or the male, or both. However, medical treatments are available that are safe and effective so that many couples can eventually become pregnant.

WWW.BOOKBAZ.IR



A. An egg and sperm are injected into the fallopian tube to encourage natural fertilization in a procedure called gamete intrafallopian transfer (GIFT). B. An alternative to GIFT is the injection of sperm directly into an egg using microscopic needles. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

Demographics

Infertility can occur in both men and women.

Description

Most couples in the United States conceive within the first six months of trying when they do so without contraceptive devices and techniques. In fact, according to the Mayo Clinic, about 85% of couples become pregnant after 12 months of trying, while about half of the remaining 15% become pregnant over the next 36 months. However, according to 2008 statistics, infertility is a problem for about 10–15% of couples at any given time. Infertility has increased as a problem over the last 40 years. Some studies pin the blame for this increase on social phenomena, including the tendency for marriage to occur at a later age, which means that couples are trying to start families at a later age. It is well known that fertility in women decreases with increasing age, as illustrated by the following statistics:

- Infertility in married women ages 16–20 = 4.5%
- Infertility in married women ages 35–40 = 31.8%
- Infertility in married women over the age of 40 = 70%.

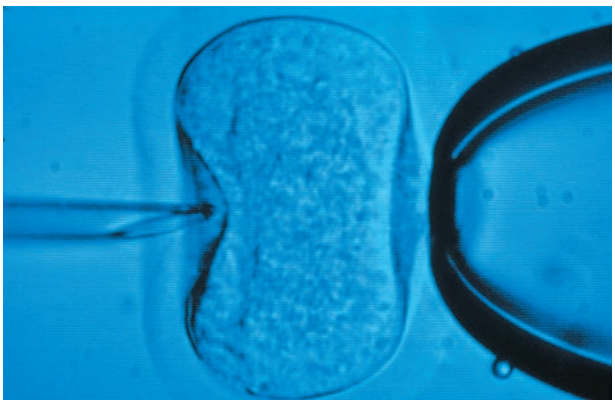
Today, individuals often have multiple sexual partners before they marry and try to have children. This increase in numbers of sexual partners has led to an increase in **sexually transmitted infections**. Scarring from these infections, especially from **pelvic inflammatory disease** (a serious infection of the female reproductive organs, most commonly caused by **gonorrhea**) seems to be in part responsible for the increase in infertility. Furthermore, use of some forms of a contraceptive called the **intrauterine device** (IUD) contributed to an increased rate of pelvic inflammatory disease, with subsequent scarring. Newer IUDs do not lead to this increased rate of infection.

To understand issues of infertility, it is first necessary to understand the basics of human reproduction. Fertilization occurs when a sperm from the male merges with an egg (ovum) from the female, creating a zygote that contains genetic material from both the father and the mother. If pregnancy is then established, the zygote will develop into an embryo, then a fetus, and ultimately a baby will be born.

The male contribution to fertilization and the establishment of pregnancy is the sperm. Sperm are small cells that carry the father's genetic material. This genetic material is contained within the oval head of the sperm. The sperm are mixed into fluid called semen, which is discharged from the penis during sexual intercourse. The whip–like tail of the sperm allows the sperm to swim up the female reproductive tract, in search of the egg it will try to fertilize.

The female makes many contributions to fertilization and the establishment of pregnancy. The ovum (plural: ova) is the cell that carries the mother's genetic material. These ova develop within the ovaries. Once a month, a single mature ovum is produced, which leaves the ovary in a process called ovulation. This ovum enters a tube (the Fallopian tube) leading to the uterus. The ovum needs to meet up with the sperm in the Fallopian tube if fertilization is to occur.

When fertilization occurs, the resulting cell (which now contains genetic material from both the mother and the father) is called the zygote. This single cell divides into multiple cells within the Fallopian tube, and the resulting cluster of cells (called a blastocyst) then moves into the womb (uterus). The uterine lining (endometrium) has been preparing itself to receive a pregnancy by growing thicker. If the blastocyst successfully reaches the inside of the uterus and attaches itself to the wall of the uterus, implantation and pregnancy have been achieved.



A microscopic image of a needle (left) injecting sperm cells directly into a human egg (center). The broad object at right is a pipette used to hold the ovum steady. *(Hank Morgan/Photo Researchers, Inc.)*

Causes and symptoms

Unlike most medical problems, infertility is an issue requiring the careful evaluation of two separate individuals, as well as an evaluation of their interactions with each other. In about 3–4% of couples, no cause for infertility is discovered. Medical studies have shown that **smoking** adds to infertility problems for both men and women. In addition, men and women who smoke are less likely to respond to infertility treatment.

The main factors involved in causing infertility, listing from the most to the least common, include:

- Male problems: 20%
- Male and female problems: 30–40%
- Female problems: 40–50%. (In these cases the problem is likely to come from conditions such as ovulation problems, pelvic adhesions and endometriosis, or cervical factors.)

Male factors

Male infertility can be caused by a number of different characteristics of the sperm. To check for these characteristics, a sample of semen is obtained and examined under the microscope, a procedure known as **semen analysis**. Four basic characteristics are usually evaluated:

- Sperm count refers to the number of sperm present in a semen sample. The normal number of sperm present in 1 mL of semen is more than 20 million. An individual with 5–20 million sperm per milliliter of semen is considered subfertile, an individual with fewer than 5 million sperm per milliliter of semen is considered infertile.
- Sperm are also examined to see how well they swim (sperm motility) and to be sure that most have normal structure.
- Not all sperm within a specimen of semen will be perfectly normal. Some may be immature, and some may have abnormalities of the head or tail. A normal semen sample will contain no more than 25% abnormal forms of sperm.
- Volume of the semen sample is important. An abnormal amount of semen could affect the ability of the sperm to successfully fertilize an ovum.

Another test can be performed to evaluate the ability of the sperm to penetrate the outer coat of the ovum. This test is conducted by observing whether sperm in a semen sample can penetrate the outer coat of a guinea pig ovum. Fertilization cannot occur, of course, but this test is useful in predicting the ability of the individual's sperm to penetrate a human ovum.

Any number of conditions result in abnormal findings in the semen analysis. Genetic problems at birth can lead to improper growth of the testicles and, thus, infertility. Men can be born with one or both testicles that have not descended properly from the abdominal cavity (where testicles develop originally) into the scrotal sac, or may be born with only one instead of the normal two testicles. When testicles have not descended from the abdominal cavity, they are exposed to a higher body temperature than when they are descended. The higher temperature reduces the production of sperm. Testicle size can be smaller than normal. Past infections (including **mumps**) can affect testicular function, as can a past injury. For instance, exposure to sexually transmitted infections (STIs), such as gonorrhea and chlamydia, can result in infertility. The presence of abnormally large veins (varicocele) in the testicles can increase testicular temperature, which decreases sperm count.

History of having been exposed to various toxins, drug use, excess alcohol use, use of anabolic **steroids**, certain medications, diabetes, thyroid problems or other endocrine disturbances, and prostate problems can have direct effects on the formation of sperm (spermatogenesis). Problems with the male anatomy can cause sperm to be ejaculated not out of the penis, but into the bladder (a process known as retrograde ejaculation). Diabetes is a medical disorder and prostate, urethral, and bladder surgeries are three procedures that can lead to retrograde ejaculation. In addition, scarring from past infections can

WWW.BOOKBAZ.IR

interfere with ejaculation. A condition called hypospadias can also cause infertility. Hypospadias occurs when the urinary opening on a man' penis is incorrectly located on its underside so that sperm cannot reach the cervix of a woman.

Sexual issues, such as **erectile dysfunction**, **premature ejaculation**, and **dyspareunia** (painful intercourse), can contribute to a male's infertility. Various psychological problems can also lead to a diminished level of fertility. **Stress** and depression can interfere with hormones that help to produce sperm. Men with long–term depression may have reduced sperm count. Physically, a man who is underweight so that he has been denied certain nutrients, such as vitamin C, zinc, and folate, may lead to infertility. On the other hand, **obesity** (being extremely overweight) in males can also be a contributing factor in infertility.

Treatment of male infertility includes addressing known reversible factors first; for example, discontinuing any medication known to have an effect on spermatogenesis or ejaculation, as well as decreasing alcohol intake, and treating thyroid or other endocrine disease. Varicoceles can be treated surgically. Testosterone in low doses can improve sperm motility.

Other treatments of male infertility include collecting semen samples from multiple ejaculations, after which the semen is put through a process that allows the most motile sperm to be sorted out. These motile sperm are pooled together to create a concentrate that can be deposited into the female partner's uterus at a time that coincides with ovulation. In cases where the male partner's sperm is proven to be absolutely unable to cause pregnancy in the female partner, and with the consent of both partners, donor sperm may be used for this process. Depositing the male partner's sperm or donor sperm by mechanical means into the female partner are both forms of artificial insemination.

Ovulatory problems

The first step in diagnosing ovulatory problems in women is to make sure that an ovum is being produced each month. A woman's morning body temperature is slightly higher around the time of ovulation. A woman can measure and record her temperatures daily and a chart can be drawn to show whether or not ovulation has occurred. Luteinizing hormone (LH) is released just before ovulation. A simple urine test can be done to check if LH has been released around the time that ovulation is expected.

Treatment of ovulatory problems depends on the cause. If a thyroid or pituitary problem is responsible, simply treating that problem can restore fertility. (The thyroid and pituitary glands release hormones that also are involved in regulating a woman's menstrual cycle.) Medication can also be used to stimulate fertility. The most commonly used of these medications are clomiphene (Clomid) and menotropin (Pergonal). These drugs increase the risk of multiple births (twins, triplets, etc.). Other possible medications include gonadotropin medications, which are injected medications made up of hormones produced in the pituitary glands. They may directly stimulate the ovaries to produce eggs. Follicle stimulating hormone (FSH) has a 95% chance of simulating ovulation in women with an ovulatory problem. However, its use does not guarantee a successful pregnancy and may lead to multiple pregnancies.

Pelvic adhesions and endometriosis

Pelvic **adhesions** and **endometriosis** can cause infertility by preventing the sperm from reaching the egg or interfering with fertilization. Pelvic adhesions are fibrous **scars**. These scars can be the result of past infections, such as pelvic inflammatory disease, or infections following abortions or prior births. Previous surgeries can also leave behind scarring.

Endometriosis may lead to pelvic adhesions. Endometriosis is the abnormal location of uterine tissue outside of the uterus. When uterine tissue is planted elsewhere in the pelvis, it still bleeds on a monthly basis with the start of the normal menstrual period. This leads to irritation within the pelvis around the site of this abnormal tissue and bleeding, and may cause scarring, along with pelvic **pain**.

Pelvic adhesions cause infertility by blocking the Fallopian tubes. The ovum may be prevented from traveling down the Fallopian tube from the ovary or the sperm may be prevented from traveling up the Fallopian tube from the uterus.

A hysterosalpingogram (HSG) can show if the Fallopian tubes are blocked. This is an x-ray examination that tests whether dye material can travel through the patient's Fallopian tubes. A few women become pregnant following this x-ray exam. It is thought that the dye material in some way helps flush out the tubes, decreasing any existing obstruction. Scarring also can be diagnosed by examining the pelvic area with a scope that can be inserted into the abdomen through a tiny incision made near the naval. This scoping technique is called **laparoscopy**.

Pelvic adhesions can be treated during laparoscopy. The adhesions are cut using special instruments. Endometriosis can be treated with certain medications, but may also require surgery to repair any obstruction caused by adhesions.

KEY TERMS

Blastocyst—A cluster of cells representing multiple cell divisions that have occurred in the Fallopian tube after successful fertilization of an ovum by a sperm. This is the developmental form that must leave the Fallopian tube, enter the uterus, and implant itself in the uterus to achieve actual pregnancy.

Cervix—The opening from the vagina, which leads into the uterus.

Embryo—The stage of development of a baby between the second and eighth weeks after conception.

Endometrium—The lining of the uterus.

Fallopian tube—The tube leading from the ovary into the uterus. Just as there are two ovaries, there are two Fallopian tubes.

Fetus—A baby developing in the uterus from the third month to birth.

Ovary—The female organ in which eggs (ova) are stored and mature.

Ovum (plural: ova)—The reproductive cell of the female that contains genetic information and participates in the act of fertilization. Also popularly called the egg.

Semen—The fluid that contains sperm, which is ejaculated by the male.

Sperm—The reproductive cell of the male, which contains genetic information and participates in the act of fertilization of an ovum.

Spermatogenesis—The process by which sperm develop to become mature sperm, capable of fertilizing an ovum.

Zygote—The result of the sperm successfully fertilizing the ovum. The zygote is a single cell that contains the genetic material of both the mother and the father.

Cervical factors

The cervix is the opening from the vagina into the uterus through which the sperm must pass. Mucus produced by the cervix helps to transport the sperm into the uterus. Injury to the cervix or scarring of the cervix after surgery or infection can result in a smaller than normal cervical opening, making it difficult for the sperm to enter. Injury or infection can also decrease the number of glands in the cervix, leading to a smaller amount of cervical mucus. In other situations, the mucus produced is the wrong consistency (perhaps too thick) to allow sperm to travel through the cervix. In addition, some women produce antibodies (immune cells) that are specifically directed to identify sperm as foreign invaders and to kill them.

Cervical mucus can be examined under a microscope to diagnose whether cervical factors are contributing to infertility. The interaction of a live sperm sample from the male partner and a sample of cervical mucus from the female partner can also be examined. This procedure is called a post–coital test.

Treatment of cervical factors includes **antibiotics** in the case of an infection, steroids to decrease production of anti–sperm antibodies, and artificial insemination techniques to completely bypass the cervical mucus.

Other causes of female infertility include: Fallopian tube damage or blockage (usually caused by inflammation), elevated prolactin (hyperprolactinemia), **polycystic ovary syndrome** (which results in the production of too much androgen hormone), early **menopause** (premature ovarian failure), **uterine fibroids** (benign tumors on the wall of the uterus), and various other medical problems (such as **sickle cell disease**, **kidney disease**, and diabetes).

Treatment

Couples can naturally increase the chances of becoming pregnant by having sexual intercourse as frequently as possible. It is especially important to have it between the tenth day and eighteen day after the beginning of a woman's menstrual period. Ovulation normally occurs, when menstruation periods are regularly spaced apart, about 14 days before menstruation begins. Therefore, sexual activity should be especially frequent from three days before to three days after ovulation. For additional help, a physician may recommend using an ovulation prediction test kit to help determine the best times for intercourse.

Assisted reproductive techniques include **in vitro fertilization** (IVF), gamete intrafallopian transfer (GIFT), and zygote intrafallopian tube transfer (ZIFT). These are usually used after other techniques to treat infertility have failed.

In vitro fertilization involves the use of a drug to induce the simultaneous release of many eggs from the female's ovaries, which are retrieved surgically. Meanwhile, several semen samples are obtained from the

WWW.BOOKBAZ.IR

male partner, and a sperm concentrate is prepared. The ova and sperm are then combined in a laboratory, where several of the ova may be fertilized. Cell division is allowed to take place up to the embryo stage. While this takes place, the female may be given drugs to ensure that her uterus is ready to receive an embryo. Three or four of the embryos are transferred to the female's uterus, and the wait begins to see if any or all of them implant and result in an actual pregnancy.

Success rates of IVF are still rather low. Most centers report pregnancy rates between 10–20%. Since most IVF procedures put more than one embryo into the uterus, the chance for a multiple birth (twins or more) is greatly increased in couples undergoing IVF.

GIFT involves retrieval of both multiple ova and semen, and the mechanical placement of both within the female partner's Fallopian tubes, where one hopes that fertilization will occur. ZIFT involves the same retrieval of ova and semen, and fertilization and growth in the laboratory up to the zygote stage, at which point the zygotes are placed in the Fallopian tubes. Both GIFT and ZIFT seem to have higher success rates than traditional IVF.

Prognosis

It is very difficult to obtain statistics regarding the prognosis of infertility because many different problems may exist within an individual or couple trying to conceive. In general, it is believed that of all couples who undergo a complete evaluation of infertility followed by treatment and therapies, about half will ultimately have a successful pregnancy. Of those couples who do not choose to undergo evaluation or treatment, about 5% go on to conceive after a year or more of infertility.

Prevention

Having fewer sexual partners and using contraceptive devices (such as **condoms**) that reduce the chances of contracting sexually transmitted infections, such as chlamydia and gonorrhea, can reduce the chances of becoming infertile. Getting a mumps **vaccination** is also an effective way to prevent infertility. Maintaining a healthy lifestyle with respect to diet and **exercise** is also helpful. Advice from your family doctor or a medical professional is beneficial in learning more about how to prevent infertility.

Infertility drugs

Definition

Infertility drugs are medicines that help bring about **pregnancy**.

Purpose

Infertility is the inability of a man and woman to achieve pregnancy after at least a year of having regular sexual intercourse without any type of birth control. There are many possible reasons for infertility, and finding the most effective treatment for a couple may involve many tests to find the problem. For pregnancy to occur, the woman's reproductive system must release eggs regularly—a process called ovulation. The man must produce healthy sperm that are able to reach and unite with an egg. Once an egg is fertilized, it must travel to the woman's uterus (womb), become implanted and remain there to be nourished.

If a couple is infertile because the woman is not ovulating, infertility drugs may be prescribed to stimulate ovulation. The first step usually is to try a drug such as clomiphene. If that does not work, human chorionic gonadotropin (hCG) may be tried, usually in combination with other infertility drugs.

Clomiphene and hCG may also be used to treat other conditions in both males and females.

Description

Clomiphene (Clomid, Milophene, and Serophene) comes in tablet form and is available only with a physician's prescription. Human chorionic gonadotropin is given as an injection, only under a physician's supervision.

Clomiphene citrate is used to increase the natural production of the hormones that stimulate ovulation in otherwise healthy women. When clomiphene is administered, the body produces higher levels of luteinizing hormone (LH), follicle stimulating hormone (FSH), and gonadotropins. These hormones induce ovulation.

Human chorionic gonadotropin (hCG) is sold under many brand names including Gonic, Pregnyl, Ovidrel, Chorex, Chorigon, and Profasi. This hormone stimulates the gonads in both men and women. In men, hCG increases androgen production. In women, it increases the levels of progesterone. Human chorionic gonadotropin can help stimulate ovulation in women.

Although some people believe that hCG can help lose weight, there is no evidence that this hormone offers any benefit in weight loss programs. Many medical organizations, such as the American Medical Association (AMA), warn about using hCG for such a purpose. Consequently, it should not be used for this purpose.

A number of other natural and synthetic hormones are used to induce ovulation. Urofollitropin (Bravelle, Fertinex) is a concentrated preparation of human hormones, while follitropin alfa (Gonal–F) and follitropin beta (Follistim) are human FSH preparations of recombinant DNA (deoxyribonucleic acid) origin. Developments in this field are continuous. For example, in June 2004, the U.S. Food and Drug Administration (FDA) approved a follitropin beta injection, called Follistim AQ Cartridge, in individualized doses for women to self–inject. Then, in 2008, the FDA approved SpermCheck Fertility test kit, made by ContraVac, which tests for sperm count in men.

Menotropins (Pergonal, Humegon, Repronex) are often given with human chorionic gonadotropin to stimulate ovulation in women and sperm production in men.

Recommended dosage

Dosage may be different for different patients. The physician who prescribed the drug or the pharmacist who filled the prescription will recommend the correct dosage.

Clomiphene must be taken at certain times during the menstrual cycle and patients should follow directions exactly. It is usually taken once a day for five days, beginning on or about day five of the menstrual cycle. However, this dosage and the times in which it is taken may be different for various individuals. Consequently, it should not be taken in dosages that are more or less than what is prescribed by the doctor. Go strictly by what the doctor says.

Precautions

Seeing a physician regularly while taking infertility drugs is important because side effects and complications can occur.

Treatment with infertility drugs increases the chance of multiple births. Although this eventuality may seem like a good thing to couples who want children very badly, multiple fetuses can cause problems during pregnancy and delivery and can even threaten the babies' survival.

Having intercourse at the proper time in the woman's menstrual cycle helps increase the chance of pregnancy. The physician may recommend using an ovulation prediction test kit to help determine the best times for intercourse.

Some people feel dizzy or lightheaded, or less alert when using clomiphene. The medicine may also cause blurred vision and other vision changes. Individuals who take clomiphene should not drive, use machines, or do anything else that might be dangerous until they have found out how the drugs affect them.

Questions remain about the safety of long–term treatment with clomiphene. Women should not have more than six courses of treatment with this drug and should ask their physicians for the most up–to–date information about its use.

Special conditions

People who have certain medical conditions or who are taking certain other medicines may have problems if they take infertility drugs. Before taking these drugs, patients should tell the physician about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to infertility drugs in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Clomiphene may cause **birth defects** if taken during pregnancy. Women who think they have become pregnant while taking clomiphene should stop taking the medicine immediately and check with their physicians.

WWW.BOOKBAZ.IR

KEY TERMS

Endometriosis—A condition in which tissue, like that normally found in the lining of the uterus, is present outside the uterus. The condition often causes pain and bleeding.

Fetus—A developing baby inside the womb.

Fibroid tumor—A noncancerous tumor formed of fibrous tissue.

Ovary—A reproductive organ in females that produces eggs and hormones.

OTHER MEDICAL CONDITIONS. Infertility drugs may make some medical conditions worse. Before using infertility drugs, people with any of these medical problems should make sure their physicians are aware of their conditions:

- Endometriosis
- Fibroid tumors of the uterus
- Unusual vaginal bleeding
- Ovarian cyst
- Enlarged ovaries
- Inflamed veins caused by blood clots
- Liver disease, now or in the past
- Depression

USE OF CERTAIN MEDICINES. Taking infertility drugs with certain other medicines may affect the way the drugs work or may increase the chance of side effects.

Side effects

When used in low doses for a short time, clomiphene and hCG rarely cause side effects. Anyone who has stomach or pelvic **pain** or bloating while taking either medicine should check with a physician immediately. Infertility drugs may also cause less serious symptoms such as hot flashes, breast tenderness or swelling, heavy menstrual periods, bleeding between menstrual periods, nausea or **vomiting**, **dizziness**, lightheadedness, irritability, nervousness, restlessness, **headache**, tiredness, sleep problems, or depression. These problems usually go away as the body adjusts to the drug and do not require medical treatment unless they continue or they interfere with normal activities.

Other side effects are possible. Anyone who has unusual symptoms after taking infertility drugs should contact a physician.

Interactions

Infertility drugs may interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes infertility drugs should let the physician know all other medicines she is taking.

Infertility therapies

Definition

Infertility is the inability of a man and a woman to conceive a child through sexual intercourse. There are many possible reasons for the problem, which can involve the man, the woman, or both partners. Various treatments, or infertility therapies, are available

that enable a woman to become pregnant; the correct one will depend on the specific cause of the infertility.

Purpose

Infertility treatment is aimed at enabling a woman to have a baby by treating the man, the woman, or both partners. During normal conception of a child, the man's sperm travels to the woman's Fallopian tubes, where, if conditions are right, it will encounter an egg that has been released from the ovary. The sperm fertilizes the egg, which will enter the uterus where it implants and begins to divide, forming an embryo. The embryo develops during **pregnancy** into a baby.

Infertility treatment attempts to correct or compensate for any abnormalities in this process that prevent the fertilization of an egg or development of an embryo.

Precautions

It is important for a couple contemplating infertility treatment to examine their own ideas and feelings about the process and consider ethical objections before the woman becomes pregnant from such treatment. Some infertility clinics recommend that couples attend at least one session with a psychologist or psychiatrist before proceeding with infertility therapy. In this way couples can freely express their concerns and learn more about what they are about to experience. It also helps to identify couples that may be having difficulties coping with the situation. Infertility support groups are also available in most areas to help with questions that arise, along with helping to provide an experienced viewpoint about infertility therapy.

Description

About 85% of women who are trying to get pregnant and use no birth control will do so within one year, and half of the other 15% become pregnant within another three years. If after one year of having sexual intercourse with no **contraception** a couple has not conceived, they should seek the advice of a physician. Tests can be performed to look for possible infertility problems.

Treating an underlying infection or illness is the first step in infertility treatment. The physician may also suggest improving general health, changing diet, reducing **stress**, and counseling.

Treatment

Low sperm count treatments

The most common cause of male infertility is failure to produce enough healthy sperm. For fertilization to occur, the number of sperm cells in the man's semen (the fluid ejected during sexual intercourse) must be sufficient, and the sperm cells must have the right shape, appearance, and activity (motility).

Defects in sperm can be caused by an infection resulting from a sexually transmitted infection (STI), a blockage caused by a varicose vein in the scrotum (varicocele), an endocrine imbalance, or problems with other male reproductive organs (such as the testicles, prostate gland, or seminal vesicles).

A **physical examination** of a man's genitals is usually the first step in identifying a low sperm count. The medical history of the man is also collected, especially noting incidences of illnesses, injuries, and recurring health problems. Semen is also examined with a **semen analysis** test. The number of sperm is counted under a microscope.

If low sperm count is the problem, it is possible to restore fertility by:

- treating any underlying infections.
- timing sex to coincide with the time the woman is ovulating, which means that the egg is released from the ovary and is beginning to travel down the Fallopian tube (the site of fertilization).
- having sex less often to build up the number of sperm in the semen.
- treating any endocrine imbalance with drugs.
- having a surgical procedure to remove a varicocele (varicocelectomy).

Fertility drugs

If infertility is due to a woman's failure to release eggs from the ovary (ovulate), fertility drugs can help bring hormone levels into balance, stimulating the ovaries and triggering egg production.

Surgical repair

In some women, infertility is due to blocked Fallopian tubes. The egg is released from the ovary, but sperm is prevented from reaching it because of a physical obstruction in the Fallopian tube. If this is the case, surgery may help repair the damage. **Microsurgery** can sometimes repair the damage to scarred Fallopian tubes if it is not too severe. Not all tube damage can be repaired, however, and most tubal problems are more successfully treated with **in vitro fertilization**.

WWW.BOOKBAZ.IR

Fibroid tumors in the uterus also may cause infertility, and they can be surgically treated. **Endometriosis**, a condition in which parts of the lining of the uterus become imbedded on other internal organs (such as the ovaries or Fallopian tubes) may contribute to infertility. It may be necessary to surgically remove the endometrial tissue to improve fertility.

Artificial insemination

Artificial insemination may be tried if sperm count is low, the man is impotent, or the woman's vagina creates a hostile environment for the sperm. The procedure is not always successful. In this procedure, semen is collected and placed into the woman's cervix with a small syringe at the time of ovulation. From the cervix, sperm can travel to the Fallopian tube where fertilization takes place. If the partner's sperm count is low, it can be mixed with donor sperm before being transferred into the uterus.

If sperm is not present in the male partner's semen, then artificial insemination can be performed using a donor's sperm obtained from a sperm bank.

Assisted reproductive technologies

Some fertility treatments require removal of eggs and/or sperm and manipulation of them in certain ways in a laboratory to assist fertilization. These techniques are called as a group: assisted reproductive technologies (ART). They have helped thousands of women each year in the United States to become pregnant so that couples can have their own biological children.

IN VITRO FERTILIZATION (IVF). When infertility cannot be treated by other means or when the cause is not known, it is still possible to become pregnant through in vitro fertilization (IVF), a costly, complex procedure that achieves pregnancy about 20% of the time. IVF is usually recommended when both Fallopian tubes are blocked, but it can be used for other problems (such as endometriosis, cervical factor infertility, and ovulation disorders).

In this procedure, a woman's eggs are removed by withdrawing them from the woman' ovaries with a special needle. Attempts are then made to fertilize the eggs with sperm from her partner or a donor. This fertilization takes place in a Petri dish in a laboratory. The fertilized egg (embryo) is then returned to the woman's uterus so that it can develop normally from that point.

Often, three to six fertilized eggs are returned at the same time into the uterus. Usually one or two of the embryos survive and grow into fetuses, but sometimes three or more fetuses result.

A child born in this method is popularly known as a "test tube baby," but in fact the child actually develops inside the mother. Only the fertilization of the egg takes place in the laboratory. The birth of the first test tube baby occurred in 1978 in the United Kingdom. As of 2014, more than 5 million babies around the world had been born with the help of in vitro fertilization, with the most active countries being Japan and the United States.

INTRACYTOPLASMIC SPERM INJECTION (ICSI). In a variation of IVF called intracytoplasmic sperm injection (ICSI), single sperm cells are injected directly into each egg with the use of a microscopic technique called micromanipulation. This process, developed in 1991 in Belgium, may be helpful for men with severe infertility (low sperm count) and also when eggs cannot be easily penetrated by sperm.

GAMETE INTERFALLOPIAN TRANSFER (GIFT). In this technique, eggs are removed from the ovaries of a woman and placed directly into one of her two Fallopian tubes to encourage fertilization to occur naturally. At least one normal Fallopian tube must be available for the procedure to work successfully. This procedure, developed by Argentine endocrinologist Ricardo Asch (1947–), is performed by means of **laparoscopy**. In laparoscopy, a small tube with a viewing lens at one end is inserted into the abdomen through a small incision. The lens allows the physician to see inside the patient on a video monitor.

ZYGOTE INTRAFALLOPIAN TRANSFER (ZIFT). If infertility is caused by a low sperm count, zygote intrafallopian transfer (ZIFT) can be tried. This technique combines GIFT and IVF. This procedure is also called a "tubal embryo transfer."

In this technique, in–vitro fertilization is first performed, so that the actual fertilization takes place and is confirmed in the laboratory. Two days later, instead of placing the embryo in the uterus, the physician performs laparoscopy to place the embryos in the Fallopian tube, much as with the GIFT procedure. The success of this technique is usually not known for about five weeks.

A woman must have at least one functioning Fallopian tube in order to participate in ZIFT.

Preparation

Couples who are having fertility problems may want to limit or avoid:

- tobacco
- alcohol

KEY TERMS

Gamete—An egg (ovum) from the female or a mature sperm from the male.

Laparoscopy—A procedure in which a viewing tube is inserted through the abdominal wall to examine a woman's reproductive organs.

Ovulation—The release of an egg from the ovary. Fertilization can occur within a day or two of ovulation.

Zygote—A fertilized egg.

- caffeine
- stress
- tight–fitting undershorts (men)
- hot tubs, saunas and steam rooms (high temperatures can kill sperm)

Risks

Women who take fertility drugs have a higher likelihood of getting pregnant with more than one child at a time, resulting in multiple pregnancies. Such pregnancies also carry the risk of low birth weight for the infants born as a result of this procedure. There are also rare but serious side effects to fertility drugs. **Birth defects** have been shown to be possible when assisted reproductive technologies are used. For instance, ovarian hyperstimulation syndrome (OHSS) may occur at a higher rate in women using infertility therapies than with other women. OHSS is a complication—directly caused by the use of fertility medications—in which the ovaries become enlarged, abdominal swelling occurs, blood pressure decreases, and other symptoms occur. Invasive procedures used with the various types of infertility therapies, as with any type of surgery, carry risk of infection, bleeding, and other complications.

Results

Typically, at least half of all couples who are infertile will respond to treatment with a successful pregnancy. For those who cannot become pregnant with treatment or insemination, surrogate parenting or adopting may be other options.

Carol A. Turkington

Influenza

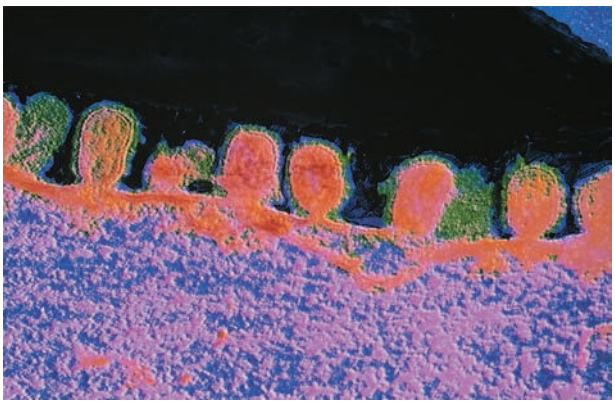
Definition

Usually referred to as the flu or grippe, influenza is a highly infectious respiratory disease. The disease is caused by certain strains of the influenza virus. When the virus is inhaled, it attacks cells in the upper respiratory tract, causing typical flu symptoms such as **fatigue**, **fever** and chills, a hacking **cough**, and body aches. Influenza victims are also susceptible to potentially life-threatening secondary infections. Although the stomach or intestinal "flu" is commonly blamed for stomach upsets and **diarrhea**, the influenza virus rarely causes gastrointestinal symptoms. Such symptoms are most likely due to other organisms such as rotavirus, *Salmonella*, *Shigella*, or *Escherichia coli*.

Description

The flu is considerably more debilitating than the **common cold**. Influenza outbreaks occur suddenly, and infection spreads rapidly. The annual death toll attributable to influenza and its complications averages 20,000 in the United States alone. In the 1918-1919 Spanish flu pandemic, the death toll reached a

WWW.BOOKBAZ.IR



A transmission electron microscopy (TEM) image of influenza viruses budding from the surface of an infected cell. *(SPL/Photo Researchers, Inc.)*

staggering 20–40 million worldwide. Approximately 500,000 of these fatalities occurred in the United States.

Influenza outbreaks occur on a regular basis. The most serious outbreaks are pandemics, which affect millions of people worldwide and last for several months. The 1918–1919 influenza outbreak serves as the primary example of an influenza pandemic. Pandemics also occurred in 1957 and 1968 with the Asian flu and Hong Kong flu, respectively. The Asian flu was responsible for 70,000 deaths in the United States, while the Hong Kong flu killed 34,000.

Epidemics are widespread regional outbreaks that occur every two to three years and affect 5–10% of the population. The Russian flu in the winter of 1977 is an example of an epidemic. A regional epidemic is shorter lived than a pandemic, lasting only several weeks. Finally, there are smaller outbreaks each winter that are confined to specific locales.

The earliest existing descriptions of influenza were written nearly 2,500 years ago by the ancient Greek physician Hippocrates. Historically, influenza was ascribed to a number of different agents, including "bad air" and several different bacteria. In fact, its name comes from the Italian word for "influence," because people in eighteenth-century Europe thought that the disease was caused by the influence of bad weather. It was not until 1933 that the causative agent was identified as a virus.

There are three types of influenza viruses, identified as A, B, and C. Influenza A can infect a range of animal species, including humans, pigs, horses, and birds, but only humans are infected by types B and C. Influenza A is responsible for most flu cases, while infection with types B and C virus are less common and cause a milder illness.

In the United States, 90% of all deaths from influenza occur among persons older than 65. Flu-related deaths have increased substantially in the United States since the 1970s, largely because of the **aging** of the American population. In addition, elderly persons are vulnerable because they are often reluctant to be vaccinated against flu.

A new concern regarding influenza is the possibility that hostile groups or governments could use the virus as an agent of bioterrorism. A report published in early 2003 noted that Type A influenza virus has a high potential for use as such an agent because of the virulence of the Type A strain that broke out in Hong Kong in 1997 and the development of laboratory methods for generating large quantities of the virus. The report recommended the stockpiling of present **antiviral drugs** and speeding up the development of new ones.

Causes and symptoms

Approximately one to four days after infection with the influenza virus, the victim is hit with an array of symptoms. "Hit" is an appropriate term, because symptoms are sudden, harsh, and unmistakable. Typical influenza symptoms include the abrupt onset of a **headache**, dry cough, and chills, rapidly followed by overall achiness and a fever that may run as high as 104°F (40°C). As the fever subsides, nasal congestion and a **sore throat** become noticeable. Flu victims feel extremely tired and weak and may not return to their normal energy levels for several days or even a couple of weeks.

Influenza complications usually arise from bacterial infections of the lower respiratory tract. Signs of a secondary respiratory infection often appear just as the victim seems to be recovering. These signs include high fever, intense chills, chest pains associated with breathing, and a productive cough with thick yellowish green sputum. If these symptoms appear, medical treatment is necessary. Other secondary infections, such as sinus or ear infections, may also require medical intervention. Heart and lung problems, and other chronic diseases, can be aggravated by influenza, which is a particular concern with elderly patients.

With children and teenagers, it is advisable to be alert for symptoms of Reye's syndrome, a rare, but serious complication. Symptoms of Reye's syndrome are **nausea and vomiting**, and more seriously, neurological problems such as confusion or **delirium**. The

SPANISH FLU EPIDEMIC (1918)

Two men wearing and advocating the use of flu masks in Paris during the Spanish flu epidemic that followed World War I. *(Topical Press AgencyGetty Images)*

Named the Spanish Flu because it was incorrectly believed to have originated in Spain, this horrible strain of influenza was a global epidemic, affecting World War I soldiers as well as civilians. Because this epidemic began during World War I, it spread quickly throughout the world as soldiers and ships moved from country to country. In 1919, President Woodrow Wilson even contracted the disease while negotiating the Treaty of Versailles. The classic flu symptoms quickly progressed to pneumonia, extremely high fevers, and cyanosis. It is now believed that the Spanish Flu actually began in the United States.

Usually, influenza has dire consequences for infants and the elderly. Surprisingly, the Spanish Flu's death rate was much higher in younger patients. Of the total number of Spanish Flu-related deaths in 1918-1919, 99% of them were people 65 or younger.

The Spanish Flu killed approximately 50 million people worldwide, causing more deaths than the World War. It has been termed "the greatest medical holocaust in history". Many experts warn that another influenza-based epidemic could be on the horizon, and recent cases of Avian Influenza have shown similiarities in the genetic code. Scientists are using tissue samples from the 1918 victims to research and develop vaccines and treatment plans in preparation for another worldwide epidemic.

syndrome has been associated with the use of **aspirin** to relieve flu symptoms.

Diagnosis

Although there are specific tests to identify the flu virus strain from respiratory samples, doctors typically rely on a set of symptoms and the presence of influenza in the community for diagnosis. Specific tests are useful to determine the type of flu in the community, but they do little for individual treatment. Doctors may administer tests, such as throat cultures, to identify secondary infections.

Since 1999, seven rapid diagnostic tests for flu have become commercially available. These tests appear to be especially useful in diagnosing flu in children, allowing doctors to make more accurate treatment decisions in less time.

Treatment

Essentially, a bout of influenza must be allowed to run its course. Symptoms can be relieved with bed rest and by keeping well hydrated. A steam vaporizer may make breathing easier, and **pain** relievers will take care of the aches and pain. Food may not seem very appetizing, but an effort should be made to consume nourishing food. Recovery should not be pushed too rapidly. Returning to normal activities too quickly invites a possible relapse or complications.

Drugs

Since influenza is a viral infection, **antibiotics** are useless in treating it. However, antibiotics are frequently used to treat secondary infections.

Over-the-counter medications are used to treat flu symptoms, but it is not necessary to purchase a medication marketed specifically for flu symptoms. Any medication that is designed to relieve symptoms, such as pain and coughing, will provide some relief. Medications containing alcohol, however, should be avoided because of the dehydrating effects of alcohol. The best medicine for symptoms is simply an analgesic, such as aspirin, **acetaminophen**, or naproxen. Without a doctor's approval, aspirin is generally not recommended for people under 18 owing to its association with Reye's syndrome, a rare aspirin-associated complication seen in children recovering from the flu.

WWW.BOOKBAZ.IR

To be on the safe side, children should receive acetaminophen or ibuprofen to treat their symptoms.

There are four antiviral drugs marketed for treating influenza. To be effective, treatment should begin no later than two days after symptoms appear. Antivirals may be useful in treating patients who have weakened immune systems or who are at risk for developing serious complications. They include amantadine (Symmetrel, Symadine) and rimantadine (Flumandine), which work against Type A influenza, and zanamavir (Relenza) and oseltamavir phosphate (Tamiflu), which work against both Types A and B influenza. Amantadine and rimantadine can cause side effects such as nervousness, **anxiety**, lightheadedness, and nausea. Severe side effects include seizures, delirium, and hallucination, but are rare and are nearly always limited to people who have kidney problems, seizure disorders, or psychiatric disorders. The new drugs zanamavir and oseltamavir phosphate have few side effects but can cause **dizziness**, jitters, and **insomnia**.

Alternatives

There are several alternative treatments that may help in fighting off the virus and recovering from the flu, in addition to easing flu symptoms.

- Acupuncture and acupressure. Both are said to stimulate natural resistance, relieve nasal congestion and headaches, fight fever, and calm coughs, depending on the acupuncture and acupressure points used.
- Aromatherapy. Aromatherapists recommend gargling daily with one drop each of the essential oils of tea tree (*Melaleuca* spp.) and lemon mixed in a glass of warm water. If already suffering from the flu, two drops of tea tree oil in a hot bath may help ease the symptoms. Essential oils of eucalyptus (*Eucalyptus globulus*) or peppermint (*Mentha piperita*) added to a steam vaporizer may help clear chest and nasal congestion.
- Herbal remedies. Herbal remedies can be used to stimulate the immune system (echinacea), as antivirals (*Hydrastis canadensis*) goldenseal and garlic (*Allium sativum*), or directed at whatever symptoms arise as a result of the flu. For example, an infusion of boneset (*Eupatroium perfoliatum*) may counteract aches and fever, and yarrow (*Achillea millefolium*) or elderflower tinctures may combat chills.
- Homeopathy. To prevent flu, a homeopathic remedy called *Oscillococcinum* may be taken at the first sign of flu symptoms and repeated for a day or two. Although oscillococcinum is a popular flu remedy in Europe, a research study published in 2003 found it to be ineffective. Other homeopathic remedies recommended vary according to the specific flu symptoms present. *Gelsemium* (*Gelsemium sempervirens*) is recommended to combat weakness accompanied by chills, a headache, and nasal congestion. *Bryonia* (*Bryonia alba*) may be used to treat muscle aches, headaches, and a dry cough. For restlessness, chills, hoarseness, and achy joints, poison ivy (*Rhus toxicodendron*) is recommended. Finally, for achiness and a dry cough or chills, *Eupatorium perfoliatum* is suggested.
- Hydrotherapy. A bath to induce a fever will speed recovery from the flu by creating an environment in the body where the flu virus cannot survive. The patient should take a bath as hot as he/she can tolerate and remain in the bath for 20–30 minutes. While in the bath, the patient drinks a cup of yarrow or elderflower tea to induce sweating. During the bath, a cold cloth is held on the forehead or at the nape of the neck to keep the temperature down in the brain. The patient is assisted when getting out of the bath (he/she may feel weak or dizzy) and then gets into bed and covers up with layers of blankets to induce more sweating.
- Traditional Chinese medicine (TCM). Practitioners of TCM recommend mixtures of herbs to prevent flu as well as to relieve symptoms once a person has fallen ill. There are several different recipes for these remedies, but most contain ginger and Japanese honeysuckle in addition to other ingredients.
- Vitamins. For adults, 2–3 g of vitamin C daily may help prevent the flu. Increasing the dose to 5–7 g per day during the flu can felp fight the infection. (The dose should be reduced if diarrhea develops.)

Prognosis

Following proper treatment guidelines, healthy people under the age of 65 usually have no long-term consequences associated with flu infection. The elderly and the chronically ill are at greater risk for secondary infection and other complications, but they can also enjoy a complete recovery.

Most people recover fully from an influenza infection, but it should not be viewed complacently. Influenza is a serious disease, and approximately 1 in 1,000 cases proves fatal.

Prevention

The Centers for Disease Control and Prevention recommend that people get an influenza vaccine injection each year before flu season starts. In the United States, flu season typically runs from late December to

KEY TERMS

Bioterrorism—The intentional use of disease-causing microbes or other biologic agents to intimidate or terrorize a civilian population for political or military reasons. Type A influenza virus could be used as an agent of bioterrorism.

Common cold—A mild illness caused by an upper respiratory viruses. Usual symptoms include nasal congestion, coughing, sneezing, throat irritation, and a low-grade fever.

Epidemic—A widespread regional disease outbreak.

Guillain-Barré syndrome—Also called acute idiopathic polyneuritis, this condition is a neurologic syndrome that can cause numbness in the limbs and muscle weakness following certain viral infections.

Pandemic—Worldwide outbreak of an infection, afflicting millions of victims.

early March. Vaccines should be received two to six weeks prior to the onset of flu season to allow the body enough time to establish immunity. Adults only need one dose of the yearly vaccine, but children under nine years of age who have not previously been immunized should receive two doses with a month between each dose.

Each season's flu vaccine contains three virus strains that are the most likely to be encountered in the coming flu season. When there is a good match between the anticipated flu strains and the strains used in the vaccine, the vaccine is 70–90% effective in people under 65. Because immune response diminishes somewhat with age, people over 65 may not receive the same level of protection from the vaccine, but even if they do contract the flu, the vaccine diminishes the severity and helps prevent complications.

The virus strains used to make the vaccine are inactivated and will not cause the flu. In the past, flu symptoms were associated with vaccine preparations that were not as highly purified as modern vaccines, not to the virus itself. In 1976, there was a slightly increased risk of developing Guillain-Barré syndrome, a very rare disorder, associated with the swine flu vaccine. This association occurred only with the 1976 swine flu vaccine preparation and has never recurred.

Serious side effects with modern vaccines are extremely unusual. Some people experience a slight soreness at the point of injection, which resolves within a day or two. People who have never been exposed to influenza, particularly children, may experience one to two days of a slight fever, tiredness, and muscle aches. These symptoms start within 6–12 hours after the **vaccination**.

It should be noted that certain people should not receive an influenza vaccine. Infants six months and younger have immature immune systems and will not benefit from the vaccine. Since the vaccines are prepared using hen eggs, people who have severe **allergies** to eggs or other vaccine components should not receive the influenza vaccine. As an alternative, they may receive a course of amantadine or rimantadine, which are also used as a protective measure against influenza. Other people who might receive these drugs are those who have been immunized after the flu season has started or who are immunocompromised, such as people with advanced HIV disease. Amantadine and rimantadine are 70–90% effective in preventing influenza.

There are two types of influenza vaccines: the flu shot and the flu mist. The flu shot consists of inactivated (killed) influenza viruses and is given by injection into the muscle. With the flu mist, the live, attenuated (weakened) influenza vaccine (LAIV) is sprayed into the nostrils, but this type of vaccination is not recommended for persons over the age of 49. Both injectable and mist vaccine typically contain three influenza viruses, two of type A virus and one of type B virus. The strains of viruses included in the vaccine change yearly based on international surveillance data of influenza cases and estimations by scientists on what types and strains of viruses will be prevalent in the coming influenza season. When the strains included in the vaccine are well matched to the strains present in the community, the vaccine usually can protect 7–9 out of 10 vaccinated persons. In elderly people, the vaccine may not work as well in preventing influenza, but will result in decrease in severity of symptoms and in the risk of health complications.

In April 2009, the U.S. Department of Health and Human Services declared a **public health** emergency regarding human cases of **H1N1 influenza A**, more commonly called swine flu. Swine flu was of special

WWW.BOOKBAZ.IR

concern for several reasons. Experts believed that the virus was a new strain of influenza with a genetic composition different from the familiar viruses that cause seasonal influenza. Because it was radically different, individuals were especially susceptible to developing serious illness. In addition, the virus often caused more intense symptoms in young, healthy people than in the elderly or the very young who are the greatest target of seasonal flu. Because the decision had already been made about which strains of seasonal flu were to be included in the vaccine for the next flu season and manufacture had already begun, a special push was made to make a separate vaccine against the swine flu. Thus, in the winter of 2009 through the 2010 flu season, people were advised to get two separate flu shots, one against seasonal flu and one against the new H1N1 influenza A.

Certain groups are strongly advised to be vaccinated because they are at increased risk for influenza-related complications:

- All people 65 years and older
- Residents of nursing homes and chronic-care facilities, regardless of age
- Adults and children who have chronic heart or lung problems, such as asthma
- Adults and children who have chronic metabolic diseases, such as diabetes and renal dysfunction, as well as severe anemia or inherited hemoglobin disorders
- Children and teenagers who are on long-term aspirin therapy
- Women who will be in their second or third trimester during flu season or women who are nursing
- Anyone who is immunocompromised, including HIV-infected persons, cancer patients, organ transplant recipients, and patients receiving steroids, chemotherapy, or radiation therapy
- Anyone in contact with the above groups, such as teachers, care givers, healthcare personnel, and family members
- Travelers to foreign countries

A person need not be in one of the at-risk categories to receive a flu vaccination. Anyone who wants to forego the discomfort and inconvenience of an influenza attack may receive the vaccine.

Influenza vaccination

Definition

An **influenza vaccination** is a vaccination used to protect individuals against the viruses that cause influenza, which is also called the flu.

Purpose

Influenza vaccination helps to protect people against getting influenza. Protection is imperfect

because the viruses that cause influenza are constantly changing (mutating). Influenza vaccines are updated every year to reflect the current stains of flu that are expected to be most prevalent, and re-vaccination is recommended every year.

Description

Every year in the United States about 226,000 people are hospitalized and 36,000 die of influenza-related complications, most often bacterial **pneumonia**, **dehydration**, or a worsening of chronic medical conditions, such as **congestive heart failure**, **asthma**, or diabetes. Ninety percent of the deaths occur in individuals 65 years and older. During influenza epidemics, hospitalization rates for older people increase two to five times compared to other seasons of the year and, more than half of the hospitalizations are people 65 and older.

An influenza vaccination is the best way to be protected from contracting influenza. Older Hispanic and African-American adults are much less likely to be vaccinated against influenza than their white counterparts. The rate of vaccination of senior citizens is about 65% in the United States. African-Americans 65 years and older lag behind whites by about 21% in getting annual vaccinations, while Hispanic Americans 65 years and older lag behind whites by 19%. In large urban areas with high levels of unvaccinated persons, there is a potential for outbreaks of influenza; thus, improving overall immunization coverage rates is essential. Studies have also shown that elderly people who choose to be vaccinated are generally in better health than those who fail to get the vaccine, so influenza control strategies should be developed to target those who are not being vaccinated. The U.S. Centers for Disease Control and Prevention (CDC) set a target date of 2010 to increase influenza vaccinations to 90% among all adults aged 65 years and older, with an emphasis on vaccinating minority groups. In the United States the influenza vaccination is provided at no cost to all senior citizens covered by Medicare.

There are two types of influenza vaccines: the flu shot and the flu mist. The flu shot consists of inactivated (killed) influenza viruses and is given by injection into the muscle. With the flu mist, the live, attenuated (weakened) influenza vaccine (LAIV) is sprayed into the nostrils, but this type of vaccination is not recommended for persons over the age of 49. Both injectable and mist vaccine typically contain three influenza viruses, two of type A virus and one of type B virus. The strain of viruses included in the vaccine change yearly based on international surveillance data of influenza cases and estimations by scientists on what types and strains of viruses will be prevalent in the coming influenza season. When the strains included in the vaccine are well matched to the strains present in the community, the vaccine usually can protect 7–9 out of 10 vaccinated persons. In elderly people, the vaccine may not work as well in preventing influenza, but will result in decrease in severity of symptoms and in the risk of health complications.

In April 2009, the U.S. Department of Health and Human Services declared a **public health** emergency regarding human cases of **H1N1 influenza A**, more commonly called swine flu. Swine flu was of special concern for several reasons. Experts believed that the virus was a new strain of influenza with a genetic composition different from the familiar viruses that cause seasonal influenza. Because it was radically different, individuals were especially susceptible to developing serious illness. In addition, the virus often caused more intense symptoms in young, healthy people than in the elderly or the very young who are the greatest target of seasonal flu. Because the decision had already been made about which strains of seasonal flu were to be included in the vaccine for the next flu season and manufacture had already begun, a special push was made to make a separate vaccine against the swine flu. Thus, in the winter of 2009 through the 2010 flu season, people were advised to get two separate flu shots, one against seasonal flu and one against the new H1N1 influenza A.

Vaccinations against influenza are especially important for those who are not in good health. The vaccination is recommended for persons who have trouble swallowing or breathing, are receiving long term steroid therapy, or who have had heart attacks, **heart disease**, lung diseases such as asthma, **emphysema**, or chronic **bronchitis**, diabetes, HIV, blood disorders such as sickle cell anemia or other **hemoglobinopathies**, kidney or **liver disease**, or weakened immune systems. Individuals with such conditions are at an increased risk of developing serious influenza-related complications. Those who are at a high risk of complications and who have not received their influenza vaccination the preceding fall or winter should be vaccinated before travel to the tropics, travel with tourist groups, or travel to the Southern Hemisphere during April through September.

Recommended dosage

The CDC recommends that the following groups be vaccinated against seasonal influenza.

- children between the ages of 6 months and 19 years
- pregnant women

WWW.BOOKBAZ.IR

KEY TERMS

Guillain-Barre Syndrome—A disorder characterized by progressive symmetrical paralysis and loss of reflexes, usually beginning in the legs. The paralysis characteristically involves more than one limb (most commonly the legs), is progressive, and usually proceeds from the end of an extremity toward the torso. Guillain-Barre usually occurs after a respiratory infection, and it is apparently caused by a misdirected immune response that results in the direct destruction of the myelin sheath surrounding the peripheral nerves or of the axon of the nerve itself.

Influenza—Commonly known as flu; an infectious disease of birds and mammals caused by viruses of the family Orthomyxoviridae (the influenza viruses); common symptoms of the disease are the chills, then fever, sore throat, muscle pains, severe headache, coughing, weakness and general feelings of illness.

Vaccination—Injection of a killed or weakened microbe in order to stimulate the immune system against the microbe, thereby preventing disease. Vaccinations, or immunizations, work by stimulating the immune system, the natural disease-fighting system of the body. The healthy immune system is able to recognize invading bacteria and viruses and produce substances (antibodies) to destroy or disable them. Vaccinations prepare the immune system to ward off a disease. To immunize against viral diseases, the virus used in the vaccine has been weakened or killed.

- all individuals age 50 or older
- people with certain chronic medical problems
- healthcare workers
- people caring for or living with children under age 5
- people caring for or living with someone at high risk for complications from influenza
- healthy individuals of any age who wish to reduce their chances of getting the flu, especially those living in group situations such as dormitories or military barracks

All persons 50 years of age and older should receive one dose intramuscularly of the inactivated seasonal influenza vaccine every year. Individuals ages 2–49 may be given flu mist rather than an injection. Ideally, vaccination should occur during the period from September to mid-November, but a vaccination received later may still be beneficial. Influenza can occur any time from November through May in the northern hemisphere, with cases usually peaking in January or February. The influenza vaccine can safely be given with other vaccines, including the pneumococcal vaccine.

For the 2009–2010 influenza season, additional vaccination against H1N1 swine flu was recommended for everyone with first responders, healthcare workers, and other high-risk individuals given priority.

Precautions

People who should not be vaccinated against influenza without first contacting a physician for advice include those who:

- have a severe allergy to chicken eggs
- have had a severe reaction to an influenza vaccination previously
- previously developed Guillain-Barre Syndrome (a very rare condition that results in weakness and paralysis of muscles of the body) within six weeks of getting an influenza vaccination

In addition, a person who has a moderate or severe illness with a **fever** should wait to get vaccinated until their symptoms decrease.

It takes up to two weeks to develop protection after the shot, with the protection from the vaccination lasting up to one year.

Side effects

Although the risk of the influenza vaccine causing serious harm or death is small and is much less than the health risks from contracting influenza, the vaccine, as with any medicine, can cause problems such as severe allergic reactions. Because the viruses in the vaccine have been killed, no one can get influenza from the vaccine. Mild problems that can occur soon after the vaccination is given and lasting 1–2 days include:

- soreness, redness, or swelling where the shot was given
- low grade fever
- aches
- chills
- general feelings of ill health
- runny nose (flu mist only)
- wheezing (flu mist only)
- sore throat (flu mist only)

More severe problems that can be associated with the influenza vaccine are life-threatening allergic reactions. These will occur within a few minutes to a few

hours after the shot. A person should stay in the clinic where the shot was given for 15 minutes, in case an immediate reaction occurs. Such reactions could include **hives**, difficulty breathing, or swelling of the throat, tongue, or lips. If a severe reaction occurs after the person leaves the clinic, the affected person should immediately be taken to an emergency healthcare facility. The chance of such an adverse reaction occurring is estimated at less than one in a million people. Any adverse reaction should be reported to the U.S. Department of Heath and Human Services through the Vaccine Adverse Event Reporting Service. If a person has had a serious reaction to a vaccine, a federal program, the National Vaccine Injury Compensation Program, is available to help pay for the care of the person harmed or injured by the shot.

Interactions

Influenza vaccines are not known to interact with any drugs or foods.

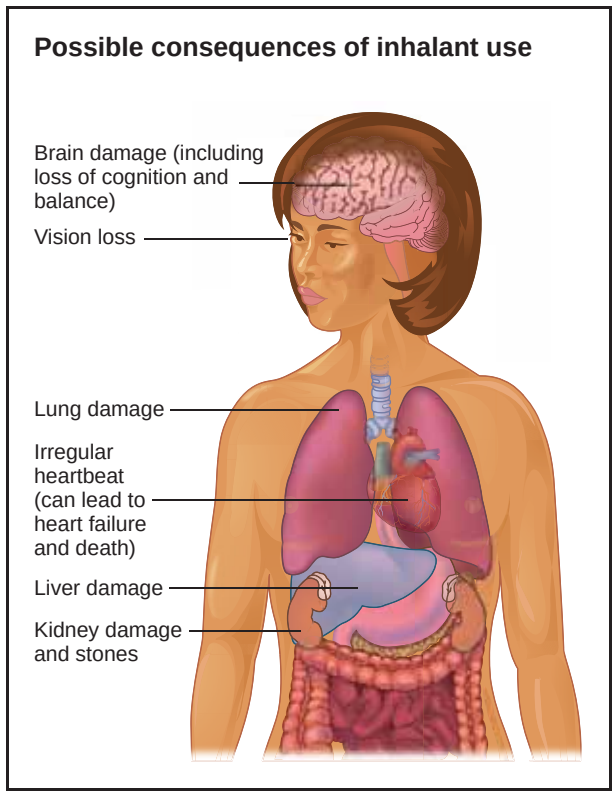
Inhalants and related disorders

Definition

Inhalants are chemicals that are inhaled through the nose or mouth for a quick "high." They include a broad range of chemicals found in hundreds of different readily available products. Inhalant intoxication, abuse, and dependence are classified as substance use disorders.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Demographics

Inhalants are one of the few substance use disorders that more often affect younger children. Because inhalants are inexpensive and readily available, they are often used by children aged 6–16, as well as by people with little money. In 2008, 2 million Americans aged 12 and over abused inhalants. It has been estimated that 10–20% of youths aged 12–17 have tried inhalants and about 6% of Americans tried inhalants prior to the fourth grade. The peak period for inhalant use appears to be the seventh through ninth grades. Inhalant use among American teens may be on the decline.

Among adults and children younger than 12, inhalant use is more common among males than females. However, there are no gender differences in inhalant use in teens between the ages of 12 and 17.

The use of inhalants and inhalant dependence are common among those who do not have access to other drugs or are otherwise isolated, such as prison

WWW.BOOKBAZ.IR

inmates. As with other substance use disorders, people who have greater access to inhalants are more likely to develop dependence. This group includes workers in industrial settings.

Description

Inhalants include volatile solvents—liquids that vaporize at room temperature—and aerosols—sprays that contain both solvents and propellants. Examples of inhalants include:

- glue
- gasoline
- paint thinner
- hairspray
- lighter fluid
- spray paint
- nail polish remover
- correction fluid
- rubber cement
- felt-tip marker fluids
- vegetable sprays
- certain cleaners

Inhalants are generally used by breathing in the vapors directly from the container ("sniffing"), by inhaling fumes from substances placed in a bag ("bagging"), or by inhaling from a cloth soaked in the substance ("huffing"). Inhalants take effect very quickly because they enter the bloodstream directly from the lungs. The "high" from inhalants is usually brief, so they are often used repeatedly over several hours. This pattern of use can be particularly dangerous, leading to unconsciousness or even death.

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) does not include use of anesthetic gases (such as nitrous oxide, chloroform, and ether) or nitrites (such as amyl and butyl nitrites) as inhalant-related disorders because they have slightly different intoxication properties. Rather, use of these substances is classified with other substance-related disorders. However, the symptoms are very similar to those of inhalants and related disorders.

Although only a small proportion of inhalant use meets the diagnostic criteria for abuse or dependence, all use of chemical inhalants constitutes abuse, since they are not being used for their intended purposes. Unlike all other substance dependencies, inhalants and related disorders may not result in clinically significant **withdrawal syndromes**. Instead inhalants are sometimes considered to be "gateway" drugs, because inhalant use often precedes the use of other substances such as alcohol, **marijuana**, or cocaine.

Risk factors

Factors associated with inhalant disorders include poverty, a history of childhood abuse, poor grades, and dropping out of school. The latter two factors may be a result of inhalant use rather than a cause. Inhalants are often used in group settings and are highly subject to peer influence.

Causes and symptoms

The symptoms of inhalant intoxication differ slightly depending on the type of inhalant, the amount used, and other factors. In general, intoxication from an inhalant usually occurs within five minutes and lasts for 5–30 minutes. Inhalants typically depress the central nervous system, with effects similar to those of alcohol, and produce euphoria, excitement, **dizziness**, and slurred speech. Inhalant intoxication can cause a feeling of floating or a sense of power.

An overdose of inhalant can result in **coma** or death. The most serious medical risk of inhalant use is "sudden sniffing death." Inhalants, especially repeated use in a single, prolonged session, can cause a rapid and irregular heartbeat or severe breathing difficulties, followed by **heart failure** and death. Sudden sniffing death can occur within minutes. Inhalant use also can cause permanent damage to the brain, lungs, kidneys, muscles, and heart. In addition to damage from the vapors themselves, many inhalants contain dangerously high levels of copper, zinc, and heavy metals.

The *DSM* requires the following criteria for a diagnosis of inhalant intoxication:

- Use: There was recent intentional inhalant use.
- Personality changes: There are significant behavioral or psychological changes during or shortly after inhaling. These might include provoking a fight, assault, using poor judgment, apathy, or impaired functioning at work or school or in a social situation.
- Inhalant-specific intoxication syndrome: Two or more of the following symptoms occur during or shortly after inhalant use or exposure: dizziness; involuntary side-to-side eye movements (nystagmus); loss of coordination; slurred speech; unsteady gait (difficulty walking); lethargy (fatigue); slowed reflexes; psychomotor retardation (moving slowly); tremor (shaking); generalized muscle weakness; blurred or double vision; stupor or coma; euphoria.

Inhalant abuse is defined as significant negative consequences from the recurrent use of inhalants without physical dependence on the substance. Abusers typically use inhalants less frequently than those with inhalant dependence, but nevertheless suffer negative consequences. For example, inhalant abuse may contribute to poor grades or school truancy. According to the *DSM*, to meet the diagnostic criteria for inhalant abuse, one or more of the following symptoms must occur and cause significant impairment or distress within a 12-month period:

- Interference with role fulfillment: Inhalant use frequently interferes with obligations at work, home, or school. Users may be unable to perform chores or pay attention at school.
- Danger to self: The user repeatedly uses inhalants in physically hazardous situations such as while driving a car.
- Legal problems: The user has recurrent legal problems related to inhalant use, such as assault arrests.
- Social problems: The user continues to use inhalants despite repeated interpersonal or relationship problems caused by or worsened by their use. For example the affected person may have arguments related to inhalant use.

Inhalant dependence or **addiction** is a syndrome in which inhalant use continues despite significant problems caused by or worsened by the use. The problems may involve employment, family relationships, and/or physical impairments such as kidney or liver damage. Users may find it difficult to stop using inhalants despite these problems. Heavy users of inhalants may develop a tolerance to the substance that suggests physical dependence. Dependent users may inhale daily or several times per week. The solitary use of inhalants is associated with heavy, prolonged use and may indicate dependency. To meet the diagnostic criteria for inhalant dependence the *DSM* requires that three or more of the following symptoms occur and cause significant impairment or distress within a 12-month period:

- Tolerance: The user has developed tolerance to the inhalant, as indicated by the same amount having less effect over time or by the need to use increasingly higher amounts to achieve the same effect. After a period of regular inhalant use, users often find that they require at least 50% more than the original amount to achieve the same effect.
- Loss of control: The user repeatedly uses a larger amount of inhalant than planned or uses over a longer period of time than planned; for example using inhalants on school days after initially limiting their use to weekends.
- Inability to stop using: The user has either unsuccessfully attempted to cut down or stop using inhalants or has a persistent desire to stop.
- Time: The user spends large amounts of time obtaining inhalants, using them, being under their influence, and recovering from their effects. Although inhalants may be readily available for very little money, they may be used repeatedly for hours every day.
- Interference with activities: The user either abandons or reduces the amount of time devoted to recreational and social activities and/or occupational activities because of inhalant use. Inhalant use may replace sports, time with friends, or work.
- Harm to self: Inhalant use continues despite physical problems, such as liver or heart damage, or psychological problems, such as depression or memory loss, that are caused by or worsened by the inhalant use.

Diagnosis

Users rarely seek diagnosis and treatment for inhalant abuse or dependence on their own. A child or adolescent may be brought to a doctor by a parent or other relative who is concerned about personality changes, a chemical odor on the child's breath, or other signs of inhalant abuse. The parent may have discovered empty containers of the inhaled substance. Sometimes inhalant use by a child or adolescent is diagnosed in a hospital emergency room after an overdose or accidental injury.

Examination

Inhalant use is sometimes diagnosed by the existence of:

- auditory, visual, or tactile hallucinations
- other perceptual disturbances, such as illusions
- delusions, such as a belief that one can fly

Inhalant disorder may be difficult to diagnose, since intoxication from alcohol, sedatives, hypnotics (medications to induce sleep), or anxiolytics (tranquilizers) can resemble inhalant intoxication. The use of other substances is not uncommon among inhalant abusers and those with inhalant dependency often have other substance abuse disorders as well. In the latter case, inhalant use is usually secondary to other substance use, since inhalants are only occasionally the primary drug of choice.

WWW.BOOKBAZ.IR

KEY TERMS

Aerosols—Sprays that contain propellants and solvents, including many household products.

Delusion—A persistent false belief held in the face of strong contradictory evidence.

Euphoria—An exaggerated state of psychological and physical well-being.

Hallucinations—False sensory perceptions; hearing sounds or seeing people or objects that are not there. Hallucinations can also affect the senses of smell, touch, and taste.

Tolerance—The body's adjustment to a drug so that it takes more and more to produce the same physiological or psychological effects.

Volatile solvents—Liquids that vaporize at room temperature, including a variety of industrial and household products and art and office-supply solvents.

Tests

Although inhalants can be detected in blood or urine samples, laboratory tests may not always confirm a diagnosis of inhalant disorder since the substances do not remain in the body for very long.

Treatment

Traditional

Inhalant intoxication is often treated in a hospital emergency room because of serious psychological or medical consequences. The latter may include **headache**, nausea, **vomiting**, severe breathing difficulties, heart failure, or injuries sustained while under the influence of inhalants, such as falls or auto accidents. Life-threatening **burns** are common since many inhalants are highly flammable. Users may also require emergency treatment for suffocation from inhaling from a plastic bag placed over the head or from **choking** on inhaled vomit.

Treatment of inhalant and related disorders usually takes a long period and involves:

- family support
- different social networks if the individual uses inhalants with friends
- new coping skills
- increased self-esteem

Prognosis

The course of inhalant use, abuse, and dependence differs somewhat depending on the user's age. Younger children who regularly abuse inhalants, especially after school and on weekends—and even children who are dependent on inhalants—often stop on their own as they get older. They may avoid substance use altogether or move on to other substances. Adults with inhalant abuse or dependence may continue to use regularly for years. Alternatively, they may binge frequently—using inhalants much more often for shorter periods of time. This pattern of use can also continue for years. Chronic inhalant users are difficult to treat because they often have other serious personal and social problems, have difficulty avoiding inhalants, and frequently relapse.

Prevention

Comprehensive prevention programs that involve families, schools, communities, and media such as television can be effective in reducing substance abuse. The focus of such programs is the avoidance of any initial contact with abused substances. This is the most effective method for preventing inhalant and related disorders.

Parents and teachers can help prevent inhalant abuse by educating children about the negative effects of inhalants and by recognizing signs of inhalant use including:

1. chemical odors on a child's breath or clothes
2. slurred speech
3. drunken or disoriented behavior
4. nausea or lack of appetite
5. inattentiveness
6. poor coordination

REVISED BY MARGARET ALIC, PhD

Inhalation therapies

Definition

Inhalation therapies are a group of respiratory, or breathing, treatments designed to help restore or improve breathing function in patients with a variety of diseases, conditions, or injuries. The treatments range from at-home **oxygen therapy** for patients with **chronic obstructive pulmonary disease** to mechanical ventilation for patients with acute **respiratory failure**. Inhalation therapies usually include the following categories:

- Oxygen therapy
- Incentive spirometry
- Continuous positive airway pressure (CPAP)
- Oxygen chamber therapy
- Mechanical ventilation
- Newborn life support

Purpose

Inhalation therapies are ordered for various stages of diseases that are causing progressive or sudden respiratory failure. Although physicians generally follow guidelines to assign specific therapy according the type and stage of a disease, the ultimate decision is based on a number of tests indicating pulmonary function and the presence or absence of oxygen in body organs and tissues.

Oxygen therapy

Oxygen therapy is most commonly ordered to support patients with **emphysema** and other chronic obstructive pulmonary disease (COPD). The oxygen therapy is usually ordered once decreased oxygen saturation in the blood or tissues is demonstrated. Oxygen therapy may also be used in the hospital setting to help return a patient's breathing and oxygen levels to normal.

Incentive spirometry

Spirometry is a diagnostic method for measuring gases and respiratory function. Incentive spirometry may be ordered to help patients practice and improve controlled breathing. It may be ordered after surgery to the abdomen, lungs, neck, or head.

Continuous positive airway pressure (CPAP)

Common uses of CPAP include **sleep apnea**, **respiratory distress syndrome** in infants, and **adult respiratory distress syndrome**. Signs of **atelectasis** (absence of gas from the lungs) or abnormalities of the lower airways may also indicate CPAP.

Oxygen chamber therapy

Oxygen chamber therapy is ordered for various causes that indicate immediate need for oxygen saturation in the blood. Divers with decompression illness, climbers at high altitudes, patients with severe carbon dioxide **poisoning**, and children or adults in acute

WWW.BOOKBAZ.IR

respiratory distress may require oxygen chamber therapy. In recent years, physicians have also used the forced pressure of oxygen chambers to help heal **burns** and other **wounds**, since the pressure under which the oxygen is delivered can reach areas that are blocked off or have poor circulation.

Mechanical ventilation

Mechanical ventilation is ordered for patients in acute respiratory distress, and is often used in an intensive care situation. In some cases, mechanical ventilation is a final attempt to continue the breathing function in a patient and may be considered life-sustaining.

Newborn life support

Newborn babies, particularly those who were premature, may require inhalation therapies immediately upon birth, since the lungs are among the last organs to fully develop. Some newborns have serious respiratory problems or birth complications, such as respiratory distress syndrome, neonatal wet lung syndrome, apnea of **prematurity** or persistent fetal circulation, which may require inhalation therapies.

Precautions

There are numerous indications for not prescribing various inhalation therapies.

Oxygen therapy

Patients and family members who smoke should not have oxygen prescribed or should avoid **smoking** in the area to prevent combustion. Sedatives should be avoided for patients on oxygen therapy.

Incentive spirometry

Patients who are unable or unwilling to properly and consistently practice incentive spirometry as prescribed should not receive this form of treatment.

Continuous positive airway pressure (CPAP)

Patients unable or unwilling to comply with the physician's instructions for use of CPAP are not likely to have it prescribed. Extremely obese patients may have less success with this form of therapy for the treatment of sleep apnea.

Oxygen chamber therapy

Complications may arise from this form of treatment and during transport to or from the oxygen chamber. Therefore, some patients may not receive enough benefit to outweigh possible complications. All patients, particularly children, must be carefully monitored.

Mechanical ventilation

Use of mechanical ventilation will be carefully weighed against benefit and possible risks. Some patients will require **sedation** to prevent fighting of the ventilator, which can increase the risk of complications.

Newborn life support

Not all infants with breathing problems will require measures as severe as mechanical ventilation. The physician will make the determination based on weight and condition of the infant. Newborns with patent ductus arteriosis, a handicap affecting the pulmonary artery, are more likely to have pulmonary hemorrhage from mechanical ventilation.

Description

Oxygen therapy

Once a patient shows hypoxemia, or decreased oxygen in arterial blood, supplemental oxygen may be ordered. The main purpose of the oxygen is to prevent damage to vital organs resulting from inadequate oxygen supply. The lowest possible saturation will be given to keep the patient's measurements at a minimum acceptable level. The oxygen is administered through a mask or nasal tube, or sometimes directly into the trachea. The amount of oxygen prescribed is measured in liters of flow per minute. Patients with chronic hypoxemia, most likely in late stages of COPD, will often receive long-term oxygen therapy.

Most patients will receive their long-term oxygen therapy through home oxygen use. A physician must prescribe home oxygen and levels will be monitored to ensure that the correct amount of oxygen is administered. Some patients will receive oxygen therapy only at night or when exercising.

The choice of home oxygen systems will vary depending on availability, cost considerations, and the mobility of the patient. Those patients who are ambulatory, especially those who work, will need a system with a small portable tank. Depending on the system chosen, frequent deliveries of oxygen and filling of portable tanks will be necessary.

In the case of respiratory distress in newborns or adults, oxygen therapy may be attempted before mechanical ventilation since it is a noninvasive and less expensive choice. Oxygen has been found effective in treating patients with other diseases such as **cystic**

fibrosis, chronic **congestive heart failure**, or other lung diseases.

Incentive spirometry

Incentive spirometry is also referred to as sustained maximal inspiration. It is designed to mimic natural sighs and yawns. A device provides positive feedback when a patient inhales at a predetermined rate and sustains the breath for a specific period of time. This helps teach the patient to take long, slow, and deep breaths. A spirometer, or equipment that measures pulmonary function, is provided to the patient and a respiratory therapist will work with the patient to demonstrate and explain the technique. Once patients show mastery of the technique, they are instructed to practice the exercises frequently on their own.

Continuous positive airway pressure (CPAP)

Patients with sleep apnea will receive CPAP to prevent upper airway collapse. It is usually administered through a tight-fitting mask as humidified oxygen. The pressure of flow is constant during both exhaling and inhaling and the level of pressure is determined based on each individual. Most patients undergoing CPAP in a hospital setting will receive continuous monitoring of some vital signs and periodic sampling of blood gas values.

Oxygen chamber therapy

Also known as hyperbaric oxygen chamber or **hyperbaric oxygen therapy** (HBO), this treatment delivers pure oxygen under pressure equal to that of 2–3 times normal atmospheric pressure. For years, this treatment has been especially effective on scuba divers who have the "bends," or decompression illness. The patient enters the chamber, a plastic cylinder-shaped structure that is normally transparent. In most cases, just one patient will enter by being rolled into the chamber on a type of stretcher. Once inside, the oxygen will be delivered under forced pressure and the patient is free to read, nap, or listen to the radio. The therapy usually lasts one hour, although it can take up to five hours in serious decompression cases. Before exiting the chamber, the pressure will eventually be lowered to normal atmospheric level.

Mechanical ventilation

In general, mechanical ventilation replaces or supports the normal ventilatory lung function of a patient. Although normally delivered in a hospital, often to treat serious illness, mechanical ventilation may be performed at home under the order and supervision of a physician and home health agency. The patient will usually be intubated and the ventilator machine takes over the breathing function.

There are several modes and methods of mechanical ventilation, each offering different advantages and disadvantages. In assist/control ventilation, the oldest mode of ventilation, the physician predetermines settings and the ventilator delivers a breath each time the patient makes an effort to inhale. In synchronized intermittent mandatory ventilation, the machine senses a patient's effort to inhale and delivers the preset amount. The amount cannot be increased by the patient's effort. Pressure-control ventilation involves the physician's selection of a peak pressure and this method is most useful for patients with obstructive airways disease. In cases of severe hypoventilation, an endotracheal tube must be inserted. If a patient will be on mechanical ventilation for more than two weeks, a tracheostomy, or surgical incision, will be performed for placement of the breathing tubes.

There are other modes of ventilation that may be used, including high-frequency ventilation, a newer technique that delivers 100–200 breaths per minute to the patient. The breaths are delivered through a humidified, high-pressure gas jet. High-frequency ventilation may be ordered when a patient does not respond to conventional mechanical ventilation or for certain conditions and circumstances.

Newborn life support

Premature infants, especially those born before the 28th week of gestation, have underdeveloped breathing muscles and immature structures within the lungs. These infants will require breathing support, often in the form of mechanical ventilation. The support delivers warm, humidified, oxygen-enriched gases either by oxygen hood or through mechanical ventilation. In serious cases, the infant may require mechanical ventilation with CPAP or positive-end expiratory pressure (PEEP) through a tightly fitting face mask or even by endotracheal intubation.

Need for continued resuscitation for newborns depends not only on gestational age, but on signs indicating ineffective breathing, including color, heart rate, and respiratory effort. CPAP will be delivered through nasal or endotracheal tubes with a continuous-flow ventilator specifically designed for infants. An alarm system alerts the neonatal staff to problems and monitoring of breathing and other vital functions will accompany the therapy. As respiratory distress syndrome begins to resolve, usually in four or five days, the type of support will be reduced accordingly and the

WWW.BOOKBAZ.IR

infant may be weaned from the ventilator and moved to only CPAP or an oxygen hood.

Preparation

Preparation for any of these treatments is normally not necessary, and in fact, these therapies may be administered as a result of an emergency situation. Some of the methods, particularly incentive spirometry, or at-home oxygen or ventilation, will require education and cooperation with a home health agency or respiratory therapist. Pretreatment testing of various indicators of respiratory function and oxygen saturation will be performed to determine exact needs of individual patients.

Aftercare

Pulmonary function tests and other tests will be performed to verify that treatments have been successful or to monitor and adjust treatments. Mechanical ventilation will require weaning from the equipment and may also require care for the area surrounding the intubation.

Risks

Inhalation therapies may carry risks, complications or side effects including:

Oxygen therapy

At-home oxygen therapy carries risk if improper care is taken to follow instructions when handling the oxygen. Patients are cautioned not to smoke near the oxygen supply and to keep the supply away from other sources that may cause electrical spark, flames, or intense heat. Patients on home oxygen therapy should avoid use of sedatives.

Incentive spirometry

The major risk associated with incentive spirometry relates to improper use. Patients must be carefully instructed in the technique and monitored periodically for compliance and improvement. Barotrauma, injury to the middle ear or sinuses caused by imbalance between the affected cavity and the outside, or ambient pressure, can result form incentive spirometry. A patient may also feel discomfort or **fatigue**.

Continuous positive airway pressure (CPAP)

The effectiveness of CPAP may be limited if patients do not cooperate. Possible side effects of CPAP include skin abrasions from the mask, leakage from the tube or mask, nasal congestion, nasal or oral dryness, or discomfort from the pressure of delivery.

Oxygen chamber therapy

Hyperbaric oxygen therapy is painless. The only risk would be associated with improper administration of the pressure levels, which should not occur, since respiratory staff and the supervising physician should be thoroughly trained in performance of this therapy. The drawback to hyperbaric oxygen treatment is the limited availability of chambers. Many cities do not have readily available chambers.

Mechanical ventilation

The biggest risk of mechanical ventilation is sometimes considered to be a patient's dependence on the machine and the difficulty of weaning the patient. The physician will carefully select and monitor the mode of ventilation, the machine's settings, and the patient's progress to prevent this complication. A patient may be left on a ventilator after sufficient progress is made to gradually wean breathing dependence.

Intubation and mechanical ventilation are frightening and uncomfortable for many patients and they may fight the ventilator. If this occurs, the physician may order a sedative to ensure cooperation and effectiveness of the therapy. Intubation often results in irritation to the trachea and larynx. Tracheostomy is associated with risk of bleeding, pneumothorax, local infection, and increased incidence of aspiration.

Newborn life support

Infants are continuously monitored to determine even small changes in breathing function. Mechanical ventilation can result in increases in respiratory distress or other complications. It is possible for the ventilator to be accidentally disconnected and staff is trained to watch for signs or alarms indicating disconnection. Mechanical ventilation increases risk of infection in premature babies. Complications of PEEP or CPAP may include pneumothorax or decreased cardiac output.

Results

Oxygen therapy

In the case of COPD, oxygen therapy does not treat the disease but can prolong life, quality of life, and onset of more serious symptoms. Effective oxygen therapy for any patient should lead to improved or sustained levels of oxygen in arterial blood.

KEY TERMS

Aspiration—Accidental suction of fluids or vomit into the respiratory system.

Cannula—A tube inserted into a cavity to serve as a channel for the transport of fluid.

Endotracheal—Placed within the trachea.

Hypoventilation—Reduced ventilation in the lungs' air sacs resulting in above normal carbon dioxide pressure.

Hypoxemia—A condition in which there is deficient oxygen supply in the blood.

Hypoxia—Low levels of oxygen in blood, tissue, or air.

Intubation—Placement of a tube into a hollow organ (such as the trachea).

Pneumothorax—Presence of gas or air in the hollow space around the lungs.

Trachea—The windpipe, or main channel by which air passes to and from the lungs.

Incentive spirometry

With proper use of incentive spirometry, the physician should observe improved pulse rate, decreased respiratory rate, improved respiratory muscle performance, and other indicators of improved function. Lung function following lung resection should show marked improvement following incentive spirometry.

Continuous positive airway pressure

Successful CPAP will result in reduction in apnea for those with sleep apnea. A study reported on in 1998 demonstrated that CPAP was effective in the majority of patients with sleep apnea, with the exception of significantly obese patients with blood gas values that were worse during waking hours at rest and at **exercise**. Hospitalized patients on CPAP therapy should show improvement in blood gas and other pulmonary measurements as expected by the treating physician.

Oxygen chamber therapy

Divers undergoing emergency treatment in a hyperbaric chamber should show immediate improvement in oxygen levels throughout the body, regardless of blood flow restrictions, after one or two treatments. Those patients receiving oxygen chamber therapy for difficult wounds may continue to receive treatments daily for several weeks before satisfactory results are reached. Patients with carbon dioxide poisoning should show improvement in or recovery of neurologic function. Results of hyperbaric chamber therapy depend largely on how quickly the patient was brought to the chamber, as well as the severity of the initial condition.

Mechanical ventilation

Successful mechanical ventilation will result in gradual decrease in dependence on the ventilator and weaning from the machine. Reduction of therapy to another form, such as CPAP or oxygen therapy, indicates that ventilation has worked as expected. In the case of COPD, exacerbation may be successfully treated with mechanical ventilation and the patient may return to home oxygen therapy. Pediatric patients will demonstrate normal growth and development as a normal result of long-term mechanical ventilation at home. Some patients, particularly those in a hospital intensive care unit, will not be able to breathe again without the ventilator and families and physicians will face tough choices about continued **life support**.

Newborn life support

Neonates will be constantly monitored to measure lung function. Those measurements will help caregivers determine if and when mechanical ventilation can be reduced and CPAP or oxygen mask begun. CPAP is considered successful when the infant's respiratory rate is reduced by 30–40%, a chest radiograph shows improved lung volume and appearance, stabilization of oxygen levels is documented and caregivers observe improvement in the infant's comfort. Evidence that there is no infection from ventilation is also considered normal. In some cases, inhalation therapy, including mechanical ventilation, will not work and the infant's parents and physicians will face tough decisions about invasive procedures with associated high risks or cessation of life support.

Insecticide poisoning

Definition

Insecticide **poisoning** is exposure to a group of chemicals designed to eradicate insects that cause affected persons to develop clinical signs that can progress to death.

Description

Insecticides belong to a group of chemicals called organophosphates used to protect against insects. Their use is popular since they are effective and do not remain in the environment, disintegrating within a few days. Organophosphates act to inhibit an enzyme in humans called acetyl cholinesterase. This enzyme functions to degrade a chemical called acetylcholine, which excites nerve cells. The resultant effect of organophosphates would be an increase in acetylcholine, thus causing initial excitation of nerve cells.

Poisoning can occur with a broad range of symptoms affecting the functioning of nerves and initial symptoms similar to the flu such as **vomiting**, abdominal **pain**, **dizziness**, and **headache**. Common names for insecticides include dichlorvos, chlorpyrifos, diazinon, fenthion, malathion, parathion, and carbamate. A special type of insecticide called paraquat is very lethal and responsible for approximately 1,000 deaths per year just in Japan. Paraquat poisoning releases oxygen free radicals that destroy lung and kidney tissues. When poisoning is suspected, a comprehensive management and assessment plan should be performed. This initial assessment should include:

- Description of toxins: names of chemical(s).
- Magnitude of exposure: determination of amount of exposure.
- Progression of symptoms: determining the progression of symptoms can provide information concerning life support and overall outcome.
- Time of exposure: knowing the time of exposure is vital since symptoms may be delayed, and it may assist to develop a management plan.

General signs and symptoms of insecticide poisoning

Symptom/sign	Common causative agents	Possible causative agents
Rotten egg odor	Sulfur	
Hypothermia	Creosote Norbormide	
Hyperthermia (fever, pyrexia)	Nitrophenols Pentachlorophenol	Borate Thallium Metaldehyde Inorganic arsenicals Chlorophenoxy compounds Cadmium dusts Naphthalene
Chills	Phosphine Arsine	
Hot sensations	Nitrophenols Chlordimeform	Pentachlorophenol
Myalgia	Paraquat Chlorophenoxy compounds	
Thirst	Pentachlorophenol Nitrophenois Inorganic arsenicals Phosphorus Phosphides Sodium fluoride Cholecalciferol Aminopyridine	Borate Endothall
Anorexia	Organophosphates Carbamate insecticides Nicotine Pentachlorophenol Hexachlorobenzene Chlordimeform Cholecalciferol	Halocarbon fumigants Nitrophenols Inorganic arsenicals Aminopyridine
Alcohol intolerance	Thiram Calcium cyanamide	
Sweet taste in the mouth	Chlordimeform	
Metallic taste in the mouth	Inorganic arsenicals Organic mercury	
Salty, soapy taste in the mouth	Sodium fluoride	

SOURCE: U.S. Environmental Protection Agency, Recognition and Management of Pesticide Poisoning, "Index of Signs and Symptoms." Available online at: http://www.epa.gov/oppfead1/safety/healthcare/handbook/handbook.htm (accessed September 8, 2014

(Table by PreMediaGlobal. Reproduced by permission of Gale, a part of Cengage Learning.)

RACHEL CARSON(1907–1964)

Rachel Carson. *(The Library of Congress.)*

Rachel Carson initially pursued an English degree, but eventually changed her college major to zoology. She was able to pair her two passions, biology and writing, into a successful career as a biologist and a writer for the Bureau of Fisheries. Upon leaving the Bureau, she was a biologist and chief editor for the U.S. Fish and Wildlife Service.

Eventually, Carson devoted all of her time to her writing—creating best-selling environmental literature classics. One of these classics, *Silent Spring*, is considered required reading for those interested in the environment. The bulk of the book details the effects of pesticides on living things.

The book quickly gained mass market appeal and appeared on the New York Times best-seller list. People became aware and concerned about their role in the environment's future. *Silent Spring* is credited with the United States' 1972 ban of DDT as well as the creation of the Environmental Protection Agency (EPA).

- Medical history: underlying diseases and therapeutic mediations may worsen toxic manifestations.

Causes and symptoms

Exposure to insecticides can occur by ingestion, inhalation, or exposure to skin or eyes. The chemicals are absorbed through the skin, lungs, and gastrointestinal tract and then widely distributed in tissues. Symptoms cover a broad spectrum and affect several organ systems:

- Gastrointestinal: nausea, vomiting, cramps, excess salivation, and loss of bowel movement control
- Lungs: increases in bronchial mucous secretions, coughing, wheezing, difficulty breathing, and water collection in the lungs (this can progress to breathing cessation)
- Skin: sweating
- Eyes: blurred vision, smaller sized pupil, and increased tearing
- Heart: slowed heart rate, block of the electrical conduction responsible of heartbeat, and lowered blood pressure
- Urinary system: urinary frequency and lack of control
- Central nervous system: convulsions, confusion, paralysis, and coma

Diagnosis

The confirmatory diagnosis for insecticide poisoning is the measurement of blood acetyl cholinesterase less than 50% of normal. The chemicals can also be detected by specific urine testing. Signs and symptoms in addition to a comprehensive poisoning assessment are essential for diagnosis. Carbamate insecticide poisoning exhibits symptoms similar to organophosphate poisoning but without central nervous system signs.

Treatment

Decontaminate exposed clothing and wash with soap and water immediately. Emergency measures may focus on ventilator support and heart monitoring. If inhalation is suspected, the patient should be removed from the site of exposure. If the eyes were the entry site, they should be flushed with large amounts of water. If the chemicals were ingested, the stomach may be washed out and **activated charcoal** may be administered. Atropine or glycopyrrolate (Robinul) is the drug of choice for carbamate insecticide poisoning. It reverses many symptoms, but is only partially effective for central nervous symptom effects such as **coma** and convulsions. A medication called Pralidoxime is also commonly indicated to reactivate acetylcholinesterase and to reverse typical symptoms due to organophosphate poisoning. Additionally, the patient is

WWW.BOOKBAZ.IR

KEY TERMS

Acetylcholine—A chemical called a neurotransmitter that functions to excite nerve cells.

Acetylcholinesterase—An enzyme that breaks down acetylcholine.

Central nervous system—Consists of the brain and spinal cord and integrates and processes information.

Enzyme—A protein that speeds up a chemical reaction, but is not consumed during the process.

Oxygen free radicals—Reactive molecules containing oxygen and can cause cell damage.

monitored for heart, lung, liver functioning, specific blood tests, and oxygen levels in blood.

Prognosis

Prognosis depends on the specific chemical of exposure, magnitude and time of exposure, progression of symptoms (severity), and onset for medical attention.

Prevention

Adherence to accepted guidelines for handling and management is the key to preventing insecticide poisoning. These may include masks, gowns, gloves, goggles, respiratory breathing machines, or hazardous material suits.

Insomnia

Definition

Insomnia is the inability to obtain an adequate amount or quality of sleep. The difficulty may be in falling asleep, remaining asleep, or waking up too early. A person may experience one or all of these symptoms. People with insomnia do not feel refreshed when they wake up. Insomnia affects more than 70 million people, according to the National Institutes of Health. The sleeplessness is a symptom that may be caused by physical or mental conditions or circumstances. Furthermore, research indicated that insomnia may also be a medical condition, according to the National Sleep Foundation (NSF).

Description

There are two main types of insomnia. One is acute insomnia (sometimes called transient insomnia). This type occurs when insomnia symptoms exist over a reasonably short period of time. The other type is chronic insomnia, which is diagnosed when the symptoms manifest themselves over a longer period (generally more than one month). Insomnia can also be classified as either primary or secondary. Primary insomnia is a disorder that cannot be attributed to another condition or disorder. Secondary insomnia can be traced back to a source, which may be a medical condition; the use of medications, alcohol, or other substances; or a mental disorder such as severe depression.

Adults need approximately seven to eight hours of sleep each night. Teenagers should get about nine hours of sleep, and infants need to sleep 16–18 hours of sleep each day. Sleep is essential for mental and physical restoration. It is a cycle with two separate states: rapid eye movement (REM), the stage in which most dreaming occurs; and non-REM (NREM). Four stages of sleep take place during NREM: stage I, when the person passes from relaxed wakefulness; stage II, an early stage of light sleep; stages III and IV, which are increasing degrees of deep sleep. Most stage IV sleep (also called delta sleep) occurs in the first several hours of sleep. A period of REM sleep normally follows a period of NREM sleep.

Disrupted sleep

Sleeplessness or insomnia may be caused by a physical condition such as **obesity**, a mental condition such as depression, shift work with irregular hours, or a traumatic event. In the days immediately after the

terrorist attacks on September 11, 2001, 47% of Americans rated their sleep as "poor," or "fair," according to NSF's "2002 Sleep in America" poll. In comparison, 27% of poll participants rated sleep as poor or fair for most nights of that year.

The NSF's 2005 poll indicated that women were more likely to experience insomnia than men. NSF explored that demographic in the "2007 Sleep in America" poll of women between the ages of 18 and 64. That study showed that sleep problems such as insomnia were experienced by 72% of working mothers and 68% of single working women. Furthermore, 74% of stay-at-home mothers displayed symptoms of insomnia during a couple nights each week.

The 2007 poll paralleled other research showed women are 1.3 more likely to report insomnia than men. They may experience sleeplessness before and at the onset of their menstrual cycle, during **pregnancy**, and **menopause**. In addition, the foundation reported that people over the age of 65 are more likely to be bothered by insomnia than younger individuals.

Furthermore, people who are divorced, widowed, or separated are more likely to have the problem than those who are married. In addition, insomnia is more frequently reported by those with lower socioeconomic status.

Insomnia is classified both by its nightly symptoms and its duration. Sleep-onset insomnia refers to difficulty falling asleep. Maintenance insomnia refers to waking frequently during the night or waking early. Insomnia is also classified in relation to the number of sleepless nights. Short-term, or transient, insomnia is a common occurrence and usually lasts only a few days. Long-term, or chronic, insomnia lasts more than three weeks. This condition increases the risk for injuries in the home, at the workplace, and while driving because the person experiences daytime sleepiness and decreased concentration ability. Chronic insomnia could also lead to **mood disorders** such as depression.

Not all disruptions in the normal pattern of sleeping and waking are considered insomnia. Such factors as **jet lag**, unusually high levels of **stress**, changing work shifts, or other drastic changes in the person's routine can all lead to sleep problems. Unless the problems are ongoing and severe enough that they are causing distress for the person in important areas of life, he or she is not considered to have insomnia.

Causes and symptoms

The symptoms of insomnia can vary greatly from person to person. Some people find that they have trouble falling asleep at night and can lie in bed for hours without being able to drift off. Others find that they fall asleep easily, but wake many times during the night. Other people awaken too early in the morning and are then unable to get back to sleep. Some people even get enough hours of sleep but find that they do not feel rested, often because their sleep is too light.

Not all people experiencing insomnia have symptoms that occur during the daytime, but many do. Some people experience such symptoms as reduced ability to concentrate or pay attention, decreased alertness, and mental sluggishness. Some people have trouble staying awake. More people think that they have these symptoms than actually do. Upon clinical examination, many people who think that they are excessively sleepy during the day actually are not.

Transient insomnia is often caused by a temporary situation in a person's life such as an argument with a loved one, a brief medical illness, or jet lag. When the situation is resolved or the precipitating factor disappears, the condition goes away, usually without medical treatment.

Prescription drugs such as **asthma** medicine, **steroids**, and anti-depressants may cause insomnia. Sleeplessness may also be a side effect of over-the-counter products such as nasal **decongestants** and appetite suppressants.

Chronic insomnia usually has different causes, and there may be more than one factor contributing to sleeplessness. Causes of insomnia include:

- A medical condition or its treatment, including sleep apnea, diabetes, arthritis, a heart condition, and asthma
- Use of substances such as caffeine, alcohol, and nicotine
- Psychiatric conditions such as mood or anxiety disorders
- Stress or depression, such as sadness caused by the loss of a loved one or a job
- A change in work shift
- A work schedule with nontraditional hours. Shift workers who may experience insomnia include medical professionals, truck drivers, the military, and people working at businesses open 24 hours a day.
- Sleep-disordered breathing, such as snoring
- Periodic jerky leg movements, *nocturnal myoclonus*, which occur just as the individual is falling asleep
- Restless legs syndrome, which involves the urge to move the legs. The person may also experience feelings such as tingling or cramping.
- Repeated nightmares or panic attacks during sleep

WWW.BOOKBAZ.IR

Excessive worrying about whether the person will be able to fall asleep may also cause insomnia. The concern creates so much **anxiety** that the individual's bedtime rituals and behavior actually trigger insomnia, a condition called psychophysiological insomnia.

Symptoms of insomnia

People who have insomnia do not start the day refreshed from a good night's sleep. They are tired. They may have difficulty falling asleep and commonly lie in bed tossing and turning for hours. Or the individual may go to sleep without a problem but wakes in the early hours of the morning. The person is either unable to go back to sleep or drifts into a restless, unsatisfying sleep. This is a common symptom in the elderly and those with depression. Sometimes sleep patterns are reversed and the individual has difficulty staying awake during the day and takes frequent naps. The sleep at night is fitful and frequently interrupted.

Demographics

There are many different opinions about how much of the general American population experiences insomnia. Estimates suggest that around 5–20% of the adult population has some form of insomnia or long-term sleeping problem. Nearly half report at least occasional sleeping problems. Accurate data are difficult to gather, as many people misperceive how much sleep they actually get and how many times they normally wake up during the night. It is generally agreed, however, that women are more likely than men to have insomnia. As people get older, they are also are more likely to experience insomnia. People who are nervous or tense are more likely to have insomnia than those who are not. Lastly, people who live near airports or other sources of nighttime as well as daytime noise have higher rates of insomnia than the general population.

Diagnosis

Insomnia is a disorder that is usually self-reported; that is, patients usually bring up the subject of sleep problems with their doctors rather than the doctor suggesting the diagnosis. There are no laboratory tests for insomnia, but the doctor may suggest keeping a sleep diary, in which the patient notes the time they went to bed, the time(s) at which they got up during the night, their activities before bed, etc. Sleep diaries can be helpful in uncovering specific factors related to the insomnia.

Insomnia, unlike some medical conditions, is easily recognizable, as people know when they are not getting enough sleep. The key to treating insomnia is determining its causes. Some people can identify sleep-inhibiting factors such as a death in the family or a hectic work schedule with too much **caffeine** consumption and not enough **exercise**. A doctor will take factors such as these into account when making a diagnosis.

The physician's diagnosis is based on the patient's reported signs and symptoms. The doctor may review a patient's **health history** or order tests to determine if a medical condition is causing the insomnia. The physician may ask if the patient is depressed, in **pain**, under stress, or taking medications, according to the NSF. The doctor may ask about disruptions in a patient's life such as working nontraditional shifts or traveling across different time zones.

It may be useful for the patient to keep a daily record for two weeks of sleep patterns, food intake, use of alcohol, caffeine, nicotine, medications, exercise, and any other information recommended by the physician. If the patient has a bed partner, information can be obtained about whether the patient snores or is restless during sleep. This information, together with a medical history and **physical examination**, can help confirm the doctor's assessment.

A wide variety of healthcare professionals can recognize and treat insomnia. When a patient with chronic insomnia does not respond to treatment, or the condition is not adequately explained by the patient's physical, emotional, or mental circumstances, then more extensive testing by a specialist in **sleep disorders** may be warranted.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), which presents the guidelines used by the American Psychiatric Association for diagnosis of disorders, in order to be diagnosed with primary insomnia, a person must experience the symptoms for at least a month, and the symptoms must cause them distress or reduce their ability to function successfully. The symptoms cannot be caused by a different sleep disorder, a medical condition, or be a side effect of medications or substance abuse.

Insomnia may also be comorbid with (occur together with) other psychiatric disorders, including **mania**, depression, and the **anxiety disorders**.

Treatment

In both alternative and conventional medicine, treatment of insomnia includes alleviating or coping with any physical and emotional problems that

contribute to the condition. Also effective is exploring changes in lifestyle that will improve the situation.

Many treatments have been explored for treating insomnia in a number of different settings. The patient may wish to consider consulting a sleep clinic or a doctor who specializes in the treatment of sleep disorders as well as their family doctor.

Behavioral and educational therapies are usually tried first, because they do not have side effects and cannot create a chemical dependence the way some sleep medications can. Many different approaches have been designed to help patients whose insomnia is linked to particular factors.

Changes in behavior

Patients can make changes in their daily routine that are simple and effective in treating insomnia. Eating a healthy diet rich in **calcium**, magnesium, and the B **vitamins** is also beneficial.

Patients should go to bed only when sleepy and use the bedroom only for sleep or sex. Activities such as reading, watching television, or snacking should take place elsewhere. If people are unable to go to sleep, they should go into another room and do some quiet activity such as reading. People should return to bed only when sleepy. Patients should set the alarm and get up every morning at the same time, no matter how much they have slept, to establish a regular sleep-wake pattern. Naps during the day should be avoided, but if absolutely necessary, then a 30-minute nap early in the afternoon may not interfere with sleep at night.

Another successful technique is called sleep-restriction therapy, restricting the time in bed to the actual time spent sleeping. This approach allows a slight sleep debt to build up, which increases the individual's ability to fall asleep and stay asleep. If a patient sleeps five hours a night, the time in bed is limited to 5–5.5 hours. The time in bed is gradually increased in small segments, with the individual rising at the same time each morning; at least 85% of the time in bed must be spent sleeping.

Mind and body relaxation

Incorporating relaxation techniques into bedtime rituals helps a person go to sleep faster and improves the quality of sleep. These, alone or in combination with other relaxation techniques, can safely promote sleepiness. Also effective are massage techniques such as **shiatsu**, the traditional Japanese form of body work. Gentle pressure is applied to points of the body to bring on sleep.

Learning to substitute pleasant thoughts for unpleasant ones (imagery training) helps reduce worrying. Another technique is using recordings that combine the sounds of nature with soft relaxing music. **Meditation**, prayer, and breathing exercises could also be effective.

Insomnia may be treated professionally through techniques such as cognitive therapy. The therapist works with the patient to discover attitudes and feelings that disrupt sleep.

Herbal remedies

Many alternative treatments are effective in treating both the symptom of insomnia and its underlying causes. Much treatment is centered on herbal remedies, but the U.S. Food and Drug Administration (FDA) does not regulate these treatments, which means that the remedies have not proven to be safe or effective. Furthermore, ingredients are not standardized to comply with regulations. People should consult with their healthcare provider or complementary medicine practitioner before taking herbal remedies. This is especially important because some remedies such as melatonin interact with herbals like valerian and prescription medicines.

Valerian

Research as of 2008 indicated that valerian may help with insomnia. People who took valerian fell asleep more quickly and experienced improved slumber. Because of the herb's sedative properties, valerian is used to treat insomnia and anxiety. It is an approved remedy in the German Commission E Monographs, a guide to herbal remedies. Approved uses include sleeping disorders caused by nervousness.

Valerian's sedative properties have been studied in animals and people. As of 2008, valerian was regarded as probably safe when taken at the recommended dosage. The remedy did not appear to disrupt sleep cycles or REM sleep.

Furthermore, a combination of valerian and hops could help with sleeplessness. Other herbs most recommended for treating insomnia include skullcap and **ginseng**. Herbal products are available in capsule, tincture, and powdered form. Some people treat insomnia by sipping a warm cup of tea made with an herb mixture such as valerian, chamomile, hops, lemon balm, passionflower, or St. John's wort.

Aromatherapy and hydrotherapy

Aromatherapy involves healing through essential oils, the aromatic extracts of plants. Essential oils may

WWW.BOOKBAZ.IR

be used for a soothing bath; applied to the face, neck, shoulders, and pillow; or diffused in air.

Hydrotherapy consists of a warm bath, scented with an essence such as rose, lavender, or marjoram. Valerian may also be added to bath water.

Dream pillows

Another form of aromatherapy involves sleeping on a dream pillow. Also known as a sleep pillow, it can be made by sewing together two 8-in. (20 cm) pieces of fabric. There should be an opening to insert a tablespoon. Herbs such as hops, chamomile, and lavender are spooned into the dream pillow, which is placed under the bed pillow.

Melatonin

Melatonin is a natural hormone that is secreted from the brain's pineal gland. The gland regulates a person's biological clock, particularly day and night cycles. Melatonin is generally used as a jet lag remedy. It may also help establish sleep patterns for shift workers. While melatonin may help people fall asleep more quickly, studies indicated limited success when it was used for treating insomnia. Melatonin is not regulated by the FDA, so the long-term effects of taking it are not known.

Traditional Chinese medicine

Traditional Chinese medicine (TCM) treatments for insomnia include **acupuncture** and herbal remedies. Acupuncture involves the insertion of needles to manipulate energy flows around the body. Acupuncture is also applied to the treatment of conditions, including anxiety.

In TCM, herbs are used as remedies in teas and other preparations. Treatments for insomnia include reishi, a medicinal mushroom available in extract form. However, the side effects of reishi could include **dizziness** and nose bleeds, so it is important to consult with a healthcare professional before taking this remedy.

Light therapy

In **light therapy**, natural or artificial light is used to boost serotonin, a neurotransmitter in the brain related to reducing anxiety. This therapy is used to treat **seasonal affective disorder**, a condition that some people experience when there is less sunlight or fewer daylight hours. Some people with this disorder feel depressed during the winter, and their spirits pick up during the summer. Light therapy is used to combat the depression experienced during the winter.

A study on the use of bright light therapy to treat insomnia was described in the July 2005 edition of the professional journal *Sleep*. The research involved 24 men diagnosed with early-morning waking insomnia. During the two nights of the study, the men were exposed to light while watching television. Some received bright light (2,500-lux white light) from 8 p.m. to midnight the first night and from 9 p.m. to 1 a.m. the following night. The other subjects were in the dim-light control group. The subjects in the bright light group said they tended to sleep longer than they did before the treatment. They woke up later. When they did waken, they went back to sleep more quickly.

Massage therapy

Massage therapy encourages relaxation by relaxing tense muscles throughout the body. It is especially helpful for restless leg syndrome, when this is a cause of insomnia. A massage once a week by a registered massage therapist may help the individual relieve stress that is causing sleeplessness.

Medications

A physician may determine that drug therapy is necessary to treat insomnia. Drugs may be prescribed if the patient is undergoing a crisis or insomnia persists after a patient has made lifestyle changes. However, drug therapy is regarded as a short-term remedy, not a solution.

Conventional medications given for insomnia include sedatives, tranquilizers, and anti-anxiety drugs. All require a doctor's prescription and may be habit-forming. They could lose effectiveness over time and can reduce alertness during the day. The medications should be taken up to four times daily or as directed for approximately three to four weeks. The dose will vary with the physician, patient, and medication. If insomnia is related to depression, then an antidepressant medication may be helpful.

Drugs prescribed for improving sleep are called hypnotics. This category includes **benzodiazepines**, which are prescribed for anxiety and insomnia. Benzodiazepines commonly prescribed for insomnia include triazolam (Halcion), tempazepam (Restoril), lorazepam (Ativan), alprazolam (Xanax), fluazepam (Dalmane), and oxazepam (Serax).

Another medication prescribed for insomnia is zolpidem tartrate (Ambien). Recently, two drugs have been approved by the FDA for long-term use. A drug called ramelteon (brand name Rozerem) has shown no

evidence of potential for abuse, dependence or withdrawal in clinical studies. Eszopiclone (brand name Lunesta) is also approved for long-term use. Rozerem and Lunesta are currently available by prescription only.

Over-the-counter sleep products include Nytol, Sominex, Unisom Nightime Tablets, and Tylenol PM. While these products are usually not addictive, some experts believe they are not very effective in sustaining stage IV sleep and can affect the quality of sleep.

Nutrition/Dietetic concerns

Calcium and magnesium are recommended as **nutritional supplements** because of their calming effects. Because these essential nutrients must be in balance with each other, they should be taken together daily with a meal. Supplemental B vitamin complex is also recommended to help relieve stress and achieve a restful state. Caffeine and alcohol should be avoided. Relaxing teas containing chamomile and/or catnip (catmint) can be consumed before bed. Herbal tinctures such as skullcap, passionflower, hops, kava kava, or valerian root are known to calm the nervous system and promote restful sleep. A natural hormone produced by the body, dehydroepisterone (DHEA), is reduced in older individuals and has been shown to improve sleep when taken as a supplement. It is available in whole food stores and in some pharmacies.

Results

Insomnia has numerous causes and treatments, so the amount of time may vary before results are seen. A prescription drug may bring immediate results to someone coping with a spouse's death. An herbal remedy may not work immediately for a person who consumed excessive amounts of caffeine to stay awake at work after a sleepless night. A procedure such as cognitive therapy may take some time as therapist and patient work to resolve issues that hinder sleep.

Research has provided information about when some treatments take effect:

- Valerian is sold commercially in the form of capsules, extracts, and teas. The capsule or extract dosage ranges from 300–600 mg. As a sleep aid, it should be taken shortly before bedtime. People who have trouble falling asleep may see results quickly. It could take from two weeks to a month before a person with chronic insomnia experiences improved sleep.
- A combination of hops and valerian at bedtime could provide a good night's sleep.
- Melatonin is taken in a dose of from 0.3–3 mg an hour before retiring. When taken as a 3-mg dose one to two hours before bed for a maximum of four to five days per week, the dietary supplement melatonin was said to be effective in shortening the time before a person fell asleep. Side effects could include nightmares and sleepwalking.
- St. John's wort can take two weeks to take effect.
- A combination of alternative therapies should bring a difference in disturbed sleep within two to four days.
- Combinations of treatments could more quickly bring about an uninterrupted night of sleep. The person who reduces caffeine intake, walks for 15 minutes, and enjoys an herbal bath may discover that that combination brings restful sleep.
- Acupuncture is said to bring some people immediate relief. In small studies, people said that after treatment that it was easier to fall asleep and they remained asleep. This treatment is safe when it is done correctly.
- Light therapy proved to be effective in the treatment of men whose insomnia caused them to wake early. In that study, the men said they experienced an immediate benefit. However, no women were studied, and the research did not include people with other types of insomnia.

Prevention

Prevention of insomnia centers around the promotion of a healthy lifestyle. A balance of rest, recreation, and exercise in combination with stress management, regular physical examinations, and a healthy diet can do much to reduce the risk. Walking is also recommended. However, exercise should be done no more than three hours before bedtime.

Also to be avoided in the evening are drinks that contain caffeine such as coffee, tea, and colas. Chocolate contains a stimulant and may keep people awake. In addition, alcohol may initially make a person sleepy. However, it could have the opposite effect a few hours later.

Maintaining a comfortable bedroom temperature, reducing noise, and eliminating light are also helpful. The bedroom should be used only for sleeping, not watching television or reading.

WWW.BOOKBAZ.IR

KEY TERMS

Biofeedback—A training technique that enables an individual to gain some element of control over involuntary body functions.

Mood disorder—A group of mental disorders involving a disturbance of mood, along with either a full or partial excessively happy (manic) or extremely sad (depressive) syndrome not caused by any other physical or mental disorder. Mood refers to a prolonged emotion.

Sleep apnea—A condition in which a person stops breathing while asleep. These periods can last up to a minute or more and can occur many times each hour. In order to start breathing again, the person must become semi-awake. The episodes are not remembered, but the following day the person feels tired and sleepy. If severe, sleep apnea can cause other medical problems.

Sleep disorder—Any condition that interferes with sleep. As of 2014, at least 84 have been identified, according to the American Sleep Disorders Association.

Exercise, relaxation, and **nutrition** should be considered ongoing preventive measures. While life brings unexpected stresses and pressures, the person who is familiar with relaxation techniques is more prepared to cope with insomnia.

Prognosis

Insomnia can be prevented or corrected in most adults, although in some cases an underlying illness will require treatment in order to correct related insomnia. **Sleep apnea** is a potentially serious disorder related to breathing difficulties and chronic lung conditions; it can be fatal if not treated.

Untreated insomnia has potentially serious consequences, including an increased risk of motor vehicle accidents, impaired school or job performance, and a high rate of absenteeism from work. Fortunately, insomnia can be treated very effectively in most patients. Treatment using a combination of approaches is usually most effective. Patients who have had insomnia once are at an increased risk for recurrent insomnia.

Insulin resistance

Definition

Insulin resistance is not a disease as such but rather a state or condition in which a person's body tissues have a lowered level of response to insulin, a hormone secreted by the pancreas that helps to regulate the level of glucose (sugar) in the body. As a result, the person's body produces larger quantities of insulin to maintain normal levels of glucose in the blood. There is considerable individual variation in sensitivity to insulin within the general population, with the most insulin-sensitive persons being as much as six times as sensitive to the hormone as those identified as most resistant. Some doctors use an arbitrary number, defining insulin resistance as a need for 200 or more units of insulin per day to control blood sugar levels. Various researchers have estimated that 3–16% of the general population in the United States and Canada is insulin-resistant; another figure that is sometimes given is 70–80 million Americans.

Insulin resistance can be thought of as a set of metabolic dysfunctions associated with or contributing to a range of serious health problems. These disorders include type 2 diabetes (formerly called adult-onset or non-insulin-dependent diabetes), the metabolic syndrome (formerly known as syndrome X), **obesity**, and **polycystic ovary syndrome**. Some doctors prefer the term "insulin resistance syndrome" to "metabolic syndrome."

Description

To understand insulin resistance, it may be helpful to have a brief account of the way insulin works in the body. After a person eats a meal, digestive juices in the small intestine break down starch or complex sugars in the food into glucose, a simple sugar. The glucose then passes into the bloodstream. When the concentration of glucose in the blood reaches a certain point, the pancreas is stimulated to release insulin into the blood. As the insulin reaches cells in muscle and fatty (adipose) tissues, it attaches itself to molecules called insulin receptors on the surface of the cells. The activation of the insulin receptors sets in motion a series of complex biochemical signals within the cells that allow the cells to take in the glucose and convert it to energy. If the pancreas fails to produce enough insulin or the insulin receptors do not function properly, the cells cannot take in the glucose and the level of glucose in the blood remains high.

The insulin may fail to bind to the insulin receptors for any of several reasons. Some persons inherit a gene mutation that leads to the production of a defective form of insulin that cannot bind normally to the insulin receptor. Others may have one of two types of abnormalities in the insulin receptors themselves. In type A, the insulin receptor is missing from the cell surface or does not function properly. In type B, the person's immune system produces autoantibodies to the insulin receptor.

In the early stages of insulin resistance, the pancreas steps up its production of insulin in order to control the increased levels of glucose in the blood. As a result, it is not unusual for patients to have high blood sugar levels and high blood insulin levels (a condition known as hyperinsulinemia) at the same time. If insulin resistance is not detected and treated, the islets of Langerhans (the insulin-secreting groups of cells) in the pancreas may eventually shut down and decrease in number.

Causes and symptoms

Causes

The reasons for the development of insulin resistance are not completely understood but several factors that contribute to it have been identified:

- Genetic factors. Insulin resistance is known to run in families. Genetic mutations may affect the insulin receptor, the signaling proteins within cells, or the mechanisms of glucose transport.

WWW.BOOKBAZ.IR

- Obesity. Being overweight keeps the muscles from using insulin properly, as it decreases the number of insulin receptors on cell surfaces.
- Low level of physical activity. Because muscle tissue takes up 95% of the glucose that insulin helps the body utilize (brain cells and blood cells do not depend on insulin to help them use glucose), inactivity further reduces the muscles ability to use insulin effectively.
- Aging. The aging process affects the efficiency of glucose transport.
- Other diseases and disorders. Some disorders—most notably Cushing syndrome and cirrhosis—and such stresses on the body as trauma, surgery, malnutrition, or severe infections speed up the breakdown of insulin or interfere with its effects.
- Certain medications. Some drugs, including cyclosporine, niacin, and the protease inhibitors used to treat HIV infection, may contribute to insulin resistance.

Symptoms

The symptoms of insulin resistance vary considerably from person to person. Some people may have no noticeable symptoms until they develop signs of **heart disease** or are diagnosed with high blood pressure during a routine checkup. Other patients may come to the doctor with extremely high levels of blood sugar (hyperglycemia) and such classical symptoms of diabetes as thirst, frequent urination, and weight loss. A small percentage of patients—most commonly women with polycystic ovary syndrome—develop a velvet-textured blackish or dark brown discoloration of the skin known as acanthosis nigricans. This symptom, which is most commonly found on the neck, groin, elbows, knees, knuckles, or armpits, is thought to appear when high levels of insulin in the blood spill over into the skin. This spillover activates insulin receptors in the skin and causes it to develop an abnormal texture and color. Acanthosis nigricans occurs more frequently in Hispanic and African American patients than in Caucasians.

Disorders associated with insulin resistance

Insulin resistance became an important field of research in the late 1980s, when doctors first began to understand it as a precondition of several common but serious threats to health. As of 2014, insulin resistance is associated with the following disorders:

- Obesity. Obesity is not only the most common cause of insulin resistance but is a growing health concern in its own right. According to the National Institutes of Health (NIH), the percentage of American adults who meet the criteria for obesity rose from 25% to 33% between 1990 and 2000—an increase of a third within the space of a decade. Obesity is a risk factor for the development of type 2 diabetes, high blood pressure, and coronary artery disease.
- Pre-diabetes and type 2 diabetes. The NIH estimates that about 6.3% of the American population has diabetes. Of these 18.3 million people, 5.2 million are undiagnosed. Type 2 diabetes is much more common than type 1, accounting for 90–95% of patients with diabetes. Diabetes increases a person's risk of blindness, kidney disease, heart disease and stroke, disorders of the nervous system, complications during pregnancy, and dental problems; it also worsens the prognosis for such infectious diseases as influenza or pneumonia. About 41 million Americans are thought to have pre-diabetes, which is a condition marked by elevated levels of blood glucose after fasting or after a 2-hour test for glucose tolerance. According to the NIH, a majority of pre-diabetic people will develop type 2 diabetes within 10 years unless they lose 5–7% of their body weight.
- Heart disease. Insulin resistance has been linked to a group of risk factors for heart disease and stroke known as the metabolic syndrome (formerly called syndrome X). The metabolic syndrome, like obesity, has become increasingly prevalent in the United States since the 1990s; in 2014, about a quarter of the general adult population is thought to have it, with the rate rising to 40% for adults over the age of 60. To be diagnosed with the metabolic syndrome, a person must have three or more of the following risk factors: a waist circumference greater than 40 in. (102 cm) in men or 35 in. (88 cm) in women; a level of blood triglycerides of 150 milligrams per deciliter (mg/dL) or higher; blood pressure of 130/85 Hg or higher; fasting blood sugar level of 110 mg/dL or higher; and a blood level of high-density lipoprotein (HDL) cholesterol (the so-called "good" cholesterol) lower than 50 mg/dL for men or 40 mg/dL for women.
- Polycystic ovary syndrome (PCOS). PCOS is an endocrine disorder that develops in 3–10% of premenopausal women as a result of the formation of cysts (small fluid-filled sacs) in the ovaries. Women with PCOS do not have normal menstrual periods; they are often infertile and may develop hirsutism (excess body hair) or other indications of high levels of androgens (male sex hormones) in the blood. This condition is called hyperandrogenism, and has been

linked to insulin resistance in women with PCOS. Weight loss in these patients usually corrects hyperandrogenism and often restores normal ovulation patterns and fertility.

Diagnosis

Patient history and physical examination

Because insulin resistance is a silent condition in many people, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) recommends that all adults over the age of 45 be tested for type 2 diabetes. People younger than 45 who are overweight and have one or more of the following risk factors should also visit their doctor to be tested:

- One or more family members with diabetes.
- High levels of triglycerides and low levels of HDL cholesterol as defined by the criteria for metabolic syndrome.
- Hypertension (high blood pressure).
- A history of smoking.
- A history of diabetes during pregnancy (gestational diabetes).
- Giving birth to a baby weighing more than 9 lb. (4 kg). In addition to increasing the mother's risk of developing type 2 diabetes, children who are large for their gestational age (LGA) at birth have an increased risk of developing insulin resistance and metabolic syndrome in later life.
- Having African American, Hispanic, Native American, or Asian American/Pacific Islander heritage.

Some signs and symptoms associated with insulin resistance can be detected by a primary care physician during a routine office visit. Blood pressure, weight, body shape, and the condition of the skin can be checked, as well as determining whether the patient meets the criteria for obesity or is less severely overweight. Obesity is determined by the patient's **body mass index**, or BMI. The BMI, which is an indirect measurement of the amount of body fat, is calculated in English units by multiplying a person's weight in pounds by 703.1, and dividing that number by the person's height in inches squared. A BMI between 19 and 24 is considered normal; 25–29 is overweight; 30–34 is moderately obese; 35–39 is severely obese; and 40 or higher is defined as morbidly obese. The doctor may also evaluate the patient for obesity in the office by measuring the thickness of the skinfold at the back of the upper arm.

The distribution of the patient's weight is also significant, as insulin resistance is associated with a so-called apple-shaped figure, in which much of the excess weight is carried around the abdomen. People whose excess weight is carried on the hips (the pear-shaped figure) or distributed more evenly on the body are less likely to develop insulin resistance. One way of measuring weight distribution is the patient's waist-to-hip ratio; a ratio greater than 1.0 in men or 0.8 in women is strongly correlated with insulin resistance.

Laboratory tests

There is no single laboratory test that can be used to diagnose insulin resistance by itself. Doctors usually evaluate individual patients on the basis of specific symptoms or risk factors. The tests most commonly used include the following:

- Blood glucose tests. A high level of blood glucose may indicate either that the body is not producing enough insulin or is not using it effectively. Two common tests used to screen for insulin resistance are the fasting glucose test and the glucose tolerance test. In the fasting glucose test, the person takes no food after midnight and has their blood glucose level measured early in the morning. Normal blood glucose levels after several hours without food should be below 100 mg/dL. If the level is between 100 and 125 mg/dL, the person has impaired fasting glucose (IFG) or pre-diabetes. If the level is over 126 mg/dL and is confirmed by a second test, the person has diabetes. In the glucose tolerance test, the person is given a sugar solution to drink and their blood glucose level is measured 2 hours later. A normal level is 140 mg/dL; 140–199 mg/dL indicates impaired glucose tolerance (IGT) or pre-diabetes, while a level of 200 mg/dL or higher indicates diabetes.
- Tests of blood insulin levels. These help to determine whether high blood glucose levels are the result of insufficient production of insulin or inefficient use of insulin.
- Lipid profile test. This test measures the amount of total cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides. Patients with insulin resistance will have high levels of LDL cholesterol and triglycerides with low levels of HDL cholesterol.
- Measurement of blood electrolytes and uric acid. Many patients with the metabolic syndrome have high blood levels of uric acid.

A highly accurate technique for measuring insulin resistance is called the euglycemic clamp technique. The patient's blood insulin level is kept (clamped) at a high but steady level by continual insulin infusion

KEY TERMS

Acanthosis nigricans—A dark brownish or blackish discoloration of the skin related to overweight and high levels of insulin in the blood. Acanthosis nigricans is most likely to develop in the groin or armpits, or around the back of the neck.

Bariatrics—The branch of medicine that deals with the prevention and treatment of obesity and related disorders.

Body mass index (BMI)—A measurement that has replaced weight as the preferred determinant of obesity. The BMI can be calculated (in English units) as 703.1 times a person's weight in pounds divided by the square of the person's height in inches.

Glucose—A simple sugar produced when carbohydrates are broken down in the small intestine. It is the primary source of energy for the body. Various tests that measure blood glucose levels are used in diagnosing insulin resistance.

Hyperandrogenism—Excessive secretion of androgens (male sex hormones).

Hyperinsulinemia—The medical term for high levels of insulin in the blood.

Insulin—A protein hormone secreted by the islets of Langerhans in the pancreas in response to eating. Insulin carries glucose and amino acids to muscle and adipose cells and promotes their efficient use and storage.

Islets of Langerhans—Special structures in the pancreas responsible for insulin secretion among other functions. They are named for Paul Langerhans, the German researcher who first identified them in 1869.

Lipids—A group of fats and fat-like substances that are not soluble in water, are stored in the body, and serve as a source of fuel for the body.

while the blood glucose level is monitored at frequent intervals. Glucose concentrations in the blood are maintained at a normal level by an adjustable-rate glucose drip. The amount of glucose needed to maintain a normal blood glucose level over a given unit of time indicates the degree of insulin resistance. This test requires complex equipment and careful monitoring; it is considered too cumbersome to use in routine screening and is used mostly by researchers.

Treatment

Lifestyle modifications

Lifestyle modifications are the first line of treatment in dealing with insulin resistance:

- Weight reduction. Losing weight increases the body's sensitivity to insulin. It is not necessary for patients to reduce their weight to the ideal levels listed on life insurance charts. In recent years, researchers have found that even a modest weight loss—usually defined as 10% of the patient's pretreatment weight—is enough to control or at least improve insulin resistance and other health complications of obesity. Weight reduction is usually accomplished by a combination of reduced calorie intake and increased physical activity. Insulin sensitivity is reported to improve within a few days of lowered calorie intake, even before the patient loses a measurable amount of weight.
- Exercise. Regular exercise improves the body's sensitivity to insulin by increasing the muscles' uptake of glucose from the bloodstream, by increasing the efficiency of the circulatory system and glucose transport, and by reducing the amount of fat around the patient's abdomen. The American Academy of Family Practice (AAFP) recommends 30 minutes of moderately intense physical activity on most or all days of the week for people diagnosed with insulin resistance. Walking is a very good form of exercise because it does not require any special equipment other than comfortable walking shoes, can be combined with doing errands, and can be done either alone or with a group of friends. Riding a bicycle is another form of exercise recommended for weight control.
- Adding foods high in fiber to the diet. A diet high in natural fiber, found in whole grains and vegetables, lowers the levels of blood insulin as well as lowering the patient's risk of developing high blood pressure.
- Quitting smoking. Giving up smoking lowers the risk of heart disease, stroke, or lung cancer as well as increasing the body's sensitivity to insulin.
- Limiting alcohol consumption. Alcohol is a source of empty calories with little nutritional value of its own.

Medications

There are several different types of medications that can be used to treat patients with abnormal blood sugar or insulin levels:

Metabolic syndrome—A group of risk factors for heart disease, diabetes, and stroke. It includes abdominal obesity, high blood pressure, high blood glucose levels, and low levels of high-density lipoprotein (HDL) cholesterol. The metabolic syndrome is sometimes called the insulin resistance syndrome.

Metabolism—The sum of an organism's physical and chemical processes that produce and maintain living tissue, and make energy available to the organism. Insulin resistance is a disorder of metabolism.

Obesity—Excessive weight gain due to accumulation of fat in the body, sometimes defined as a BMI of 30 or higher, or body weight greater than 30% above one's desirable weight on standard height-weight tables.

Pancreas—A large gland located behind the stomach near the spleen that secretes digestive enzymes into the small intestine and insulin into the bloodstream.

Syndrome—In general, a set of symptoms that occur together as signs of a disease or disorder.

Syndrome X—A term that was sometimes used for metabolic syndrome when the syndrome was first identified in the 1960s.

Triglycerides—Fatty compounds synthesized from carbohydrates during the process of digestion and stored in the body's adipose (fat) tissues. High levels of triglycerides in the blood are associated with insulin resistance.

Type 2 diabetes mellitus—One of the two major types of diabetes mellitus, characterized by late age of onset (30 years or older), insulin resistance, high levels of blood sugar, and little or no need for supplemental insulin. It was formerly known as adult-onset or non-insulin-dependent diabetes.

- Biguanides. Biguanides are drugs that improve the body's sensitivity to insulin by lowering the absorption of glucose in the small intestine, decreasing the liver's production of glucose, and increasing the uptake of glucose in muscle and fatty tissues. Metformin (Glucophage), a drug used in the treatment of type 2 diabetes, is the most commonly used biguanide in treating insulin resistance. It has also been studied as a possible treatment in preventing or delaying the onset of type 2 diabetes.
- Thiazolidinediones. These drugs stimulate glucose uptake in the muscles and fatty tissues by activating specific receptors in the cell nucleus. They also lower blood insulin levels in patients with hyperinsulinemia. The thiazolidinediones include pioglitazone (Actos) and rosiglitazone (Avandia).
- Glucocorticoids. These drugs may be given to patients with insulin resistance caused by anti-insulin antibodies produced by their immune system. Prednisone (Deltasone) is the most commonly used glucocorticoid.
- Insulin itself. Some patients with insulin resistance benefit from injectable insulin to reduce their blood sugar levels.

The FDA has not approved any drugs for the treatment of insulin resistance by itself. For this reason, the American Diabetes Association does not recommend treating insulin resistance with medications unless the patient has already been diagnosed with diabetes.

The patient's doctor may also prescribe medications to treat specific health problems associated with insulin resistance. These drugs may include **diuretics** and other medications to lower blood pressure; **aspirin** to reduce the risk of **heart attack**; medications to lower the levels of **triglycerides** and LDL **cholesterol** in the blood; and weight-control drugs. The drugs most frequently prescribed to help patients lose weight are orlistat (Xenical) and sibutramine (Meridia).

Acanthosis nigricans may be treated with topical preparations containing Retin-A, 20% urea, or salicylic acid; however, many patients find that the skin disorder improves by itself following weight loss.

Surgery

Insulin resistance by itself does not require surgical treatment; however, patients who have already developed heart disease may require coronary artery bypass surgery. In addition, very obese patients—those with a BMI of 40 or higher—may benefit from **bariatric surgery**. Bariatric surgery includes such procedures as **vertical banded gastroplasty** and **gastric bypass**, which limit the amount of food that the stomach can contain.

Alternatives

Some alternative treatments for insulin resistance and type 2 diabetes have been studied by the Agency for Healthcare Research and Quality (AHRQ). One

WWW.BOOKBAZ.IR

study reported in 2004 that **omega-3 fatty acids**, a dietary supplement commonly derived from fish, canola, or soybean oil, did not appear to have any significant effect on blood sugar levels or blood insulin levels in patients diagnosed with type 2 diabetes or the metabolic syndrome. An earlier study of **Ayurvedic medicine**, the traditional medical system of India, reported in 2001 that certain herbs used to make Ayurvedic medicines, such as fenugreek, holy basil, *Coccinia indica*, and *Gymnema sylvestre* appear to be effective in lowering blood sugar levels and merit further study. The AHRQ report also noted that the Ayurvedic practice of combining herbal medicines with **yoga** and other forms of physical activity should be investigated further.

Other alternative treatments for insulin resistance and type 2 diabetes include chromium supplements, **ginseng**, **biofeedback**, and **acupuncture**. The connection between chromium supplementation and insulin resistance is that the body needs chromium to produce a substance called glucose tolerance factor, which increases the effectiveness of insulin. Further studies need to be done before recommendations about dietary chromium as a treatment for insulin resistance can be made.

Prognosis

Since insulin resistance is a condition that precedes the appearance of symptoms of a number of different disorders, its prognosis depends in part on the patient's age, ethnicity, family history, and severity of any current health problems. Some patients diagnosed with insulin resistance eventually develop type 2 diabetes, but it is not yet known why the others do not; for example, some patients do not develop diabetes in spite of a high degree of insulin resistance. What is known at present is that weight reduction and **exercise** can control or even reverse insulin resistance in many people.

Prevention

Genetic factors contributing to insulin resistance cannot be changed as of 2014.

With regard to lifestyle factors, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) reported the findings of a study of the effects of lifestyle changes or metformin on the incidence of diabetes in a group of over 3,200 overweight people with impaired glucose tolerance, which is a risk factor for developing type 2 diabetes. The researchers found that the subjects in the lifestyle modification group, who lowered their food intake and took 30-minute walks five days a week, had a 58% lower incidence of diabetes. The subjects who received metformin had a 31% lower incidence of diabetes. Lifestyle changes were most effective in volunteers over the age of 60, while metformin was most effective in younger subjects. In short, the 2002 study confirmed the beneficial effects of lowered food intake and increased activity as preventive measures against type 2 diabetes.

Another important part of preventing insulin resistance is patient education. A number of resources on weight control and exercise written for the general public are available from the Weight-Control Information Network (WIN) on the NIDDK website at http://win.niddk.nih.gov/publications/physical.htm. Some pamphlets are available in Spanish as well as English. Patient education materials on insulin resistance in relation to heart disease and diabetes can be downloaded free of charge from the American Heart Association and American Diabetes Association websites.

Integrative medicine

Definition

Integrative medicine, or IM, is a newer term used to describe the incorporation of complementary and alternative (CAM) treatments within conventional medicine. It is increasingly used in place of the terms "complementary" and "alternative," which many feel have too many preconceived notions associated with them. IM is also known as integrated medicine or integrative health.

No single brief definition of IM is universally accepted as of 2014. The National Center for Complementary and Alternative Medicine (NCCAM) defines IM simply as care that "combines conventional and complementary approaches in a coordinated way." The Bravewell Collaborative, a private foundation that supports research into IM, defines it as "an approach to care that puts the patient at the center and addresses the full range of physical, emotional, mental, social, spiritual, and environmental influences that affect a person's health." As defined by the University of Arizona's Center for Integrative Medicine, IM is "healing-oriented medicine that takes account of the whole person, including all aspects of lifestyle; [that] emphasizes the therapeutic relationship between practitioner and patient, is informed by evidence, and makes use of all appropriate therapies."

Description

Origins

The relationship between IM and conventional medicine is complex, both in terms of the sheer number and variety of CAM approaches and in terms of the history of so-called mainstream medicine. Following the standardization of American medical education and its emphasis on scientific or science-based treatments following the Flexner Report of 1910 (a major commentary that gave rise to modern medical education), alternative approaches to healthcare—including naturopathy and homeopathy—were driven underground, and most of the schools that offered instruction in these approaches were closed. What is now considered mainstream or conventional medicine dominated healthcare in North America from the 1920s through the 1960s.

In the late 1960s and 1970s, various alternative medical systems and practices began to resurface in the United States and Canada, as well as Western Europe. This development was in part the result of the so-called New Age movement, which was influenced by a revival of astrology, alchemy, and a general fascination with the occult, along with consciousness research, interest in holistic healing, and investigation of Eastern religions. In addition, some Westerners who traveled to India or to the Far East to study Buddhist **meditation** practices or Hindu **yoga** returned with an appreciation of Ayurveda or **traditional Chinese medicine**. The New Age emphasis on holistic or natural healing practices also led to a renewed interest in such Western alternative healing traditions as herbalism, naturopathy, and homeopathy.

By 1992, the growing interest in alternative medicine in North America led the National Institutes of Health (NIH) to establish the Office of Alternative Medicine (OAM), which was renamed NCCAM in 1998. In the years following, mainstream medical schools began to add courses in CAM to their curricula.

WWW.BOOKBAZ.IR

The next stage was the establishment of integrative medicine centers, such as those at the University of Maryland School of Medicine, which was founded in 1991, and at the University of Arizona College of Medicine, which was founded in 1994. These centers serve to educate medical professionals, as well as the general public, about IM, and offer clinical consultations to patients. The IM center at the University of Maryland also offers clinical care.

In 1999, representatives from eight medical centers and university-related medical schools with integrative medicine programs met for the first time to discuss working together to expand and develop the field of IM and to enlist support for it within academic medicine. By 2002, interest in forming an organization led to the establishment of the Consortium of Academic Health Centers for Integrative Medicine, or CAHCIM. As of 2014, CAHCIM has 57 academic medical centers and affiliate institutions as members across the United States, Canada, and Mexico. Members include the Mayo Clinic and the medical schools of Duke, Harvard, Johns Hopkins, the University of Pennsylvania, and Yale. CAHCIM states its present mission as "to advance the principles and practices of integrative healthcare within academic institutions." This includes advancing integrative healthcare curricula, research, and clinical care; and informing healthcare policy.

Purpose

In general, IM is used to manage chronic health complaints rather than traumatic injuries or acute emergencies. Chronic health complaints include such things as **sleep disorders**, **anxiety**, stress-related illnesses, chronic **fatigue**, menopausal symptoms, arthritis and other musculoskeletal disorders, and lifestyle issues encompass **smoking**, **obesity**, and other issues. The following eight principles are cited by many IM practitioners and clinics as a summary of their practice and ideals:

- The patient and the physician are partners in healing.
- All the factors that influence the patient's wellbeing are taken into account. These include body, mind, spirit, and the patient's community.
- The physician uses all relevant methods of treatment to assist the body's innate healing abilities.
- Natural and noninvasive interventions that have been shown to be effective are used whenever possible.
- Good medicine is based on good science: It continues to ask questions and is open to new discoveries and paradigms.
- Health promotion and prevention of illness are just as important as the treatment of existing health issues.
- Integrative healthcare is personalized in order to address the individual's unique needs, health issues, and circumstances.
- Physicians who practice integrative medicine exemplify its principles and commit themselves to ongoing self-exploration and self-development.

How it works

IM emphasizes a highly personalized approach to care. Most IM clinics begin with a patient consultation, during which the physician takes a detailed medical history, reviews the patient's current health issues, and asks about his or her expectations and desired outcomes. The physician then suggests a treatment plan tailored to the patient's present condition. Nonconventional treatments offered by clinics may include **guided imagery**, meditation, **hypnotherapy**, progressive relaxation, **Reiki**, **acupuncture**, **chiropractic**, **massage therapy**, holistic **psychotherapy**, integrative weight management program, or other approaches.

Reasons for considering integrative medicine

People who are interested in integrative medicine may have one or more reasons for consulting an IM clinic or practitioner. These may include:

- The person has grown up in a country or belongs to an ethnic group in which alternative medical systems have a long history and are considered standard care. This is particularly true of people from China, India, or Southeast Asia, and for members of some Native American tribes.
- The person has had what he or she considers are bad experiences with conventional medical care or its practitioners, and prefers to try another approach.
- The person wants to be an equal partner with the physician during their course of treatment, and finds that an integrative approach to healthcare facilitates this type of relationship.
- The person wants treatment modalities that will help them relieve emotional stress or the side effects of conventional medications or surgery without having to take tranquilizers or other mood-altering prescription drugs.
- The person prefers to use treatments that are natural and noninvasive whenever possible.
- The person is seeking methods of pain control that have a lower risk of dependency or addiction.

KEY TERMS

Alternative medicine—Any nonconventional treatment or substance that is used in place of mainstream medical or surgical treatment.

Ayurveda—The traditional medical system of India.

Chiropractic—A form of manipulative therapy that emphasizes the adjustment and realignment of joints and muscles. Chiropractic is most often used as an alternative treatment for low back pain.

Complementary medicine—A nonconventional therapy that is used together with or alongside mainstream treatment.

Homeopathy—A system of alternative medicine that arose in Germany in the late eighteenth century that emphasizes treating the symptoms of a given disease with highly dilute remedies made from substances that cause the symptoms of the disease in healthy people.

Naturopathy—A type of alternative medicine maintaining that humans have an innate vital force that can be fostered by noninvasive treatments, encouragement of natural healing, and minimal use of surgery and drugs.

Personalized medicine—The use of genetic information and other new discoveries to customize medical diagnosis and treatment for the individual patient. Integrative medicine is considered one approach to personalized medicine.

Reiki—A spiritual practice that developed in Japan in the 1920s that is considered a form of energy therapy. Reiki practitioners believe that they can convey healing energy to others through stylized hand positions that can be placed on or near the patient.

Traditional Chinese medicine (TCM)—The medical system of mainland China that is thousands of years old. When used as a complete system, it combines herbal medicines, dietary treatments, massage, acupuncture, and physical exercise (qigong and tai chi).

- Some cancer patients who have not benefited from conventional surgery, chemotherapy, or radiation therapy are willing to try integrative treatment methods that specifically target cancer.

Proponents of IM note that integrative medicine neither rejects conventional medicine nor accepts alternative therapies uncritically. For instance, part of the mission of the CAHCIM is to disseminate information on "rigorous scientific research," and its member researchers continue to do that work to determine the validity of various treatment options.

Costs and insurance coverage

The cost of integrative medicine treatment depends, to some extent, on the specific treatment modalities that are used together with conventional medicine. Some nonconventional treatments, such as nutritional counseling, chiropractic treatments, and acupuncture may be covered by insurance, but consumers will have to pay out of pocket for others. Consumers should consult with their insurance carrier to determine which treatments are covered, and to what extent.

Risks

Relatively few risks are associated with integrative medicine, provided that the IM practitioner is trained in conventional medicine, and that the patient keeps his or her primary care doctor informed of all treatments provided by the IM practitioner. The most commonly reported complication is interactions between herbal preparations used in traditional Chinese medicine (such as St. John's Wort) and standard prescription medications (such as antidepressants) or surgical **anesthesia**, and for this reason, patients should be diligent in informing their primary care doctors about their use of these preparations. Another risk is undertaken by patients who refuse conventional treatments or surgery, and rely solely on alternative therapies.

Rebecca J. Frey, Ph.D.
REVISED BY LESLIE MERTZ, Ph.D.

Intellectual disability

Definition

Intellectual disability or intellectual developmental disorder (IDD), referred to as intellectual disability in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*), is a developmental disability that first appears in children under the age of 18. It is defined as a level of intellectual functioning (as measured by standard intelligence tests) that is well below average and results in significant limitations in daily living skills (adaptive functioning). The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*, 2013) proposes to rename intellectual disability as intellectual developmental disorder (IDD) and define it as "a disorder that includes both a current intellectual deficit and a deficit in adaptive functioning with onset during the developmental period."

IDD is not a mental illness in the usual sense but rather a disorder defined in order to identify groups of people who need social support and special educational services to carry out tasks of everyday living. On October 5, 2010, "Rosa's Law" went into effect in the United States. Named for a child with IDD living in Maryland, the law requires federal agencies to remove the terms mentally retarded or mental retardation from official documents and replace them with "individual with an intellectual disability" and "intellectual disability."

Demographics

The prevalence of intellectual disability in North America is a subject of heated debate. It is thought to be between 1% and 3% depending upon the population, methods of assessment, and criteria of assessment that are used. Many people believe that the actual prevalence is probably closer to 1%, and that the 3% figure is based on misleading mortality rates; cases that are diagnosed in early infancy; and the instability of the diagnosis across the age span. If the 1% figure is accepted, however, it means that about 3 million people with intellectual disability live in the United States. The three most common causes of intellectual disability, accounting for about 30% of cases, are **Down syndrome**, **fragile X syndrome**, and **fetal alcohol syndrome**. Males are more likely than females to have an intellectual disability in a 1.5:1 ratio, primarily because of the association with fragile X.

Description

IDD begins in childhood or adolescence before the age of 18. In most cases, it persists throughout adult life. A diagnosis of IDD is made if an individual has an intellectual functioning level well below average, as well as significant limitations in two or more adaptive skill areas. Intellectual functioning level is defined by standardized tests that measure the ability to reason in terms of mental age (intelligence quotient or IQ). Intellectual disability is generally defined as an IQ score below 70–75. Adaptive skills is a term that refers to skills needed for daily life. Such skills include the ability to produce and understand language (communication); practical skills needed for activities of daily living (ADLs); use of community resources; health, safety, leisure, self-care, and social skills; self-direction; functional academic skills (reading, writing, and arithmetic); and job-related skills.

In general, children with intellectual and developmental impairments reach such developmental milestones as walking and talking much later than children in the general population. Symptoms of intellectual disability may appear at birth or later in childhood. The child's age at onset depends on the suspected cause of the disability. Some people with a mild intellectual disability might not be diagnosed before entering pre-school or kindergarten. These children typically have difficulties with social, communication, and functional academic skills. Children who have a neurological disorder or illness such as encephalitis or **meningitis** may suddenly show signs of cognitive impairment and adaptive difficulties.

DSM-IV categories

The level of impairment varies in severity. The *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, text revision (*DSM-IV-TR*), the diagnostic standard for mental healthcare professionals in the United States, classifies four different degrees of intellectual disability: mild, moderate, severe, and profound. These categories are based on the person's level of functioning. The *DSM-5* has proposed changes in the categories of severity of IDD. The *DSM-5* website states as of mid-2011 that "Recommendations for severity criteria for this disorder are forthcoming." The present *DSM-IV* categories of severity are as follows:

- Mild intellectual disability: Approximately 85% of people who fall into the *DSM-IV* categories of intellectual disability are in the mild category. Their IQ scores range from 50–70, and they can often learn academic skills up to about the sixth-grade level. They can become fairly self-sufficient and in some cases live independently with community and social support.
- Moderate intellectual disability: About 10% of people with intellectual disability are considered moderately disabled. People in this category have IQ scores ranging from 35–55. They can carry out work and self-care tasks with moderate supervision. They typically acquire communication skills in childhood and are able to live and function successfully within the community in such supervised environments as group homes.
- Severe intellectual disability: About 3–4% of people with intellectual disability are classified as severe. People in this category have IQ scores of 20–40. They may master very basic self-care skills and some communication skills. Many people with this level of impairment can live in a group home.
- Profound intellectual disability: Only 1–2% of people with intellectual disability are classified as profoundly disabled, meaning that they have IQ scores under 20–25. They may be able to develop basic self-care and communication skills with appropriate support and training. Their disability is often caused by an accompanying neurological disorder. People with profound intellectual disability need high levels of structure and supervision.

Reasons for changes in DSM-5

The primary reason given by the authors of *DSM-5* for changing the name of the disorder is greater consistency with international opinion and the position of the American Association on Intellectual and

WWW.BOOKBAZ.IR

Developmental Disabilities (AAIDD). This organization, formerly known as the American Association on Mental Retardation, or AAMR, has developed a widely accepted diagnostic classification system for intellectual disability. In this system, intellectual disability is defined in terms of the environment and context in which the person functions. The AAIDD offers five assumptions that are necessary for defining the presence of an intellectual disability. First, a mental health practitioner must consider the limitations of functioning in a community environmental context, including the person's age group and culture. Second, cultural and linguistic differences and differences in behavioral, sensory, and other factors should be considered. Third, strengths should be given consideration along with weaknesses. Fourth, the purpose of identifying limitations is to determine what supports the person's needs. The fifth assumption is that when the appropriate supports are available, the quality of life and functional ability of a person with an intellectual disability will improve. The AAIDD has pushed for changing the name of the disorder because of the stigma associated with the term mental retardation.

Other reasons for the changes in *DSM-5* include the need to exclude inaccurate testing as a factor in evaluating persons for IDD; the use of factor analysis to provide greater accuracy in measuring a person's adaptive functioning; and the need for greater accuracy in measuring a person's overall level of functioning. The basic cutoff point (an IQ of 70 or below) will remain unchanged.

Causes and symptoms

Causes

The cause of IDD cannot be identified in about 40% of cases. The following sections discuss known biological and environmental factors that can cause IDD.

GENETIC FACTORS. Hereditary factors are the most common single cause of IDD and are involved in about 30% of cases. The disorder may be caused by an inherited genetic abnormality, such as fragile X syndrome. Fragile X, a defect in the X chromosome in which a repeated group of letters in the DNA sequence reaches a certain threshold number that results in impairment, is the most common inherited cause of IDD. Such single-gene disorders as **phenylketonuria** (PKU) and other inborn errors of metabolism may also cause IDD if they are not discovered and treated early, although testing of infants for PKU is required at birth, and problems associated with this disorder can be avoided through dietary measures. Abnormalities in chromosome number can also be the cause of IDD. The presence of an extra chromosome 18 (trisomy 18) or chromosome 21 (trisomy 21 or Down syndrome) will result in some level of intellectual disability. In addition, there may be only a partial extra chromosome as a result of accidents at the cellular level, which sometimes results in milder forms of IDD compared to complete trisomies.

PRENATAL AND PERINATAL ILLNESSES AND ISSUES. Fetal alcohol syndrome (FAS) affects one in 3,000 children in Western countries. It is caused when mothers drink heavily during the first 12 weeks (trimester) of **pregnancy**. Some studies have shown that even moderate alcohol use during pregnancy may cause learning disabilities in children. Drug abuse and cigarette **smoking** during pregnancy have also been linked to intellectual disability.

Maternal infections and such illnesses as glandular disorders, **rubella**, **toxoplasmosis**, and cytomegalovirus (CMV) infection can result in IDD in the child, among many other problems, if the developing fetus is exposed. When the mother has high blood pressure (**hypertension**) or develops toxemia (also called pregnancy-induced hypertension or **preeclampsia**) during pregnancy, the flow of oxygen to the fetus may in some cases be reduced, potentially resulting in brain damage and IDD.

Birth defects that cause physical deformities of the head, brain, and central nervous system frequently cause IDD. A neural tube defect, for example, is a birth defect in which the neural tube that forms the spinal cord does not close completely. This defect, which occurs with varying levels of severity, may cause children to develop an accumulation of cerebrospinal fluid inside the skull (**hydrocephalus**). The pressure on the brain resulting from hydrocephalus can lead to changes that cause learning impairment.

CHILDHOOD ILLNESSES AND INJURIES. **Hyperthyroidism**, whooping **cough**, chicken pox, **measles**, and Hib disease (a bacterial infection caused by *Haemophilus influenzae* type B) may cause intellectual disability if they are not treated adequately. An infection of the membrane covering the brain (meningitis) or an inflammation of the brain itself (encephalitis) can cause swelling that in turn may cause brain damage and IDD. **Traumatic brain injury** caused by a blow to the head or by violent shaking of the upper body (**shaken baby syndrome**) may also cause brain damage and IDD in children.

ENVIRONMENTAL FACTORS. Neglected infants who are not provided with the mental and physical stimulation required for normal development may irreversible learning impairment. Children who live in

KEY TERMS

Activities of daily living (ADLs)—A general term for routine activities of self-care (e.g., brushing teeth, dressing oneself, bathing) and functioning independently (e.g., managing money, preparing meals, cleaning house).

Adaptive functioning—A term used to describe a person's having the intellectual, social, and practical skills needed to live independently.

Cytogenetics—The branch of genetics concerned with the structure and function of the individual cell, particularly its chromosome content.

Stigma—Any personal attribute that causes a person to be socially shamed, avoided, or discredited. Mental disorders are a common cause of stigma.

poverty and/or suffer from **malnutrition**, unhealthy living conditions, abuse, and improper or inadequate medical care are at higher risk. Exposure to lead or mercury can also cause IDD. Many children have developed **lead poisoning** from eating the flaking lead-based paint often found in older buildings.

Symptoms

Low IQ scores and limitations in adaptive skills are the hallmarks of IDD, as is failure to reach normal developmental milestones. Aggression, self-injury, and **mood disorders** are sometimes associated with the disability. The severity of the symptoms and the age at which they first appear depend on the cause. Children with IDD reach developmental milestones significantly later than expected, if at all. If the disorder is caused by chromosomal or other genetic disorders, it is often apparent from infancy. If IDD is caused by childhood illnesses or injuries, learning and adaptive skills that were once easy may suddenly become difficult or impossible to master.

Diagnosis

Examination

If IDD is suspected, a comprehensive **physical examination** and medical history should be done immediately to discover any organic cause of symptoms. Such conditions as hyperthyroidism and PKU are treatable if discovered early enough when the progression of IDD can be stopped and, in some cases, partially reversed. If a neurological cause, such as brain injury or **epilepsy**, is suspected, the child may be referred to a neurologist or neuropsychologist for testing.

A complete medical, family, social, and educational history is compiled from existing medical and school records (if applicable) and from interviews with parents.

Tests

In many cases of mild IDD, the disorder is not identified until the child starts school. Schoolchildren are given intelligence tests to measure their learning abilities and intellectual functioning. Such tests include the Stanford-Binet Intelligence Scale, the Wechsler Intelligence Scales, the Wechsler Preschool and Primary Scale of Intelligence, and the Kaufman Assessment Battery for Children. For infants, the Bayley Scales of Infant Development may be used to assess motor, language, and problem-solving skills. Interviews with parents or other caregivers are used to assess the child's daily living, muscle control, communication, and social skills. The Woodcock-Johnson Scales of Independent Behavior and the Vineland Adaptive Behavior Scales (VABS) are frequently used to evaluate these skills.

Procedures

Recent advances in cytogenetics and microscopy have made the detection of chromosomal abnormalities after birth much more accurate. To investigate the possibility of a genetic disorder, the doctor will obtain a sample of cells from the child's blood or skin. The cells are cultured in the laboratory and prepared for examination under a microscope by one of several purification, preservation, and staining techniques. Analysis of the chromosomes in the cell must be done by a board-certified specialist in cytogenetics.

In addition, **amniocentesis** (often called amnio) can be performed on fetal cells found in the amniotic fluid in the early second trimester of pregnancy. A sample of the amniotic fluid that surrounds a fetus in the womb is collected through a pregnant woman's abdomen using a needle and syringe. Tests performed on fetal cells found in the amniotic fluid can reveal the presence of Down syndrome as well as many types of genetic disorders. Amniocentesis is recommended for women who will be older than 35 on their due date.

One alternative to amniocentesis now in general use is **chorionic villus sampling** (CVS), which can be performed as early as the eighth week of pregnancy. CVS can be riskier and is more expensive. The procedure involves the removal of a small piece of placenta

WWW.BOOKBAZ.IR

tissue (chorionic villi) from the uterus during early pregnancy to screen the baby for genetic defects.

Treatment

Federal legislation entitles children with intellectual impairments and developmental disabilities to free testing and appropriate, individualized education and skills training within the school system from ages 3 to 21. For children under the age of three, many states have established early intervention programs that assess children, make recommendations, and begin treatment programs. Many day schools are available to help train children with developmental and intellectual impairments in skills such as bathing and feeding themselves. Extracurricular activities and social programs are also important in helping children and adolescents who have developmental and intellectual impairments gain self-esteem. Special interventions (usually some form of behavioral therapy) may be needed for children with IDD who have problems with aggression.

Training in independent living and job skills is often begun in late adolescence or early adulthood. The level of training depends on the degree of impairment. People with mild levels of functional and intellectual impairment can often learn the skills needed to live independently and hold outside jobs. People with a great level of impairment may require supervised community living in group homes or other residential settings.

Family therapy can help relatives of people with intellectual disabilities develop coping skills. It can also help parents deal with feelings of guilt or anger. A supportive and warm home environment is essential to help people with intellectual disabilities reach their full potential.

Prognosis

People with mild to moderate intellectual disability are frequently able to achieve some self-sufficiency and to lead happy and fulfilling lives. To reach these goals, they need appropriate and consistent educational, community, social, family, and vocational supports. The outlook is less promising for those with severe to profound disability. Studies have shown that these people have a shortened life expectancy. The diseases that are usually associated with severe IDD may cause a shorter life span. People with Down syndrome will develop the brain changes that characterize Alzheimer's disease in later life and may develop the clinical symptoms of this disease as well. One additional complication in assessing the future health status and life expectancy of children with IDD is their unequal access to high-quality healthcare.

Prevention

Immunization against diseases such as measles and Hib prevents many of the illnesses that can cause IDD. In addition, all children should undergo routine developmental screening as part of their pediatric care. Screening is particularly critical for those children who may be neglected or undernourished or may live in disease-producing conditions. Newborn screening and immediate treatment for PKU and hyperthyroidism can usually catch these disorders early enough to prevent adverse intellectual and developmental effects.

Good prenatal care can also be preventive. Pregnant women should be educated about the risks of alcohol and drug consumption and the need to maintain good **nutrition** during pregnancy. Tests such as an ultrasonography can determine whether a fetus is developing normally.

Intermittent claudication

Definition

Intermittent claudication is a **pain**, cramping, or weakness in the legs (usually the calf muscle of one or both lower limbs, although it can sometimes occur in the arms), especially when exercising such as walking or climbing stairs. The pain, which occurs because of reduced blood flow through the limbs, is intermittent and goes away when the person rests. It is a type of arterial occlusive disease. Intermittent claudication is also called **angina** cruris or sometimes simply as claudication and is a symptom of peripheral artery disease.

Demographics

People age 50 years or older are at risk of intermittent claudication. The risk increases with age. Statistically, 5% of men and 2.5% of women experience symptoms of this condition, according to the **Vascular Disease** Foundation (VDF). Many people with this condition have **cholesterol** plaque build-up in the leg's arteries. **Smoking** raises the risk, as do high blood pressure, **obesity**, lack of **exercise**, and diabetes.

Description

Claudication comes from the Latin word (*cludicare*) that means "to limp," and the condition is characterized by intermittent pain, usually of the leg muscles but not the joints. Poor circulation produces the pain. The legs do not receive the oxygen-rich (oxygenated) blood supply needed for activities like walking and exercising. The decreased blood flow is caused by the narrowing or damage of arteries that bring blood to the legs and feet. Most patients also have cholesterol plaque in the arteries of their legs.

The leg pain produced by claudication is usually experienced as cramping in the thighs, calves, hips, and feet. The pain stops several minutes after the person rests, but returns when the person performs activities that use the leg muscles. If untreated,

WWW.BOOKBAZ.IR

claudication is no longer intermittent and occurs when a person is resting.

Intermittent claudication is the main symptom of peripheral arterial disease (PAD), which is also known as **peripheral vascular disease** or occlusive arterial disease. Intermittent claudication is an early symptom of the condition that affects peripheral arteries, those blood vessels located outside the heart. PAD is caused by arteriosclerosis, the narrowing and hardening of the arteries. According to the National Heart, Lung, and Blood Institute, about 10% of people with PAD also have intermittent claudication.

Women with diabetes are much more likely to experience PAD as those without diabetes, according to the American Diabetes Association (ADA). Furthermore, intermittent claudication is related to a two to three times increased risk of coronary **heart disease**, **stroke**, or cardiac failure in men with diabetes, according to the association.

Causes and symptoms

Intermittent claudication is caused by poor circulation and is experienced in a person's muscle groups. It affects the peripheral arteries that convey oxygen-rich blood from the heart to the legs. A person with this condition feels pain shortly after beginning to exercise. Walking may trigger the pain in an inactive person. Activities such as climbing stairs, walking rapidly or dancing can cause the pain to increase.

The person feels the pain as tightness in the calf, thigh, or buttocks. The pain stops after the person rests for several minutes. However, it returns when the person reaches the exertion level that previously produced the pain.

Intermittent claudication is the primary symptom of PAD, the condition causing reduced flow of blood and oxygen to tissues. If the intermittent condition is not treated, the person will find that resting does not relieve pain. As arteries become more clogged, the person could feel pain even when not exercising. Symptoms include cold or numb feet and toes, poor balance when standing, a drop in leg strength, sores that heal slowly, and **erectile dysfunction** (**impotence**).

The most common cause of intermittent claudication is atherosclerosis. It involves atherosclerotic lesions of the limbs. Such lesions reduce the amount of blood to the muscles of the lower legs. The symptoms of atherosclerosis, and of intermittent claudication, are:

- Cyanosis (blue discoloration of skin, especially toes or fingers).
- Pain, cramping, burning/aching feeling, tightness, or weakness, especially in the low extremities (legs, feet, calves, hips, or buttocks), while walking or exercising.
- Deteriorate changes such as shiny skin and hair loss.
- Decreased body temperature; including a feeling of cold and a look of pallor.
- Sores on lower legs, feet, toes, arms, or elsewhere.
- Impotence (men).

In the advanced stages of PAD, the person experiences pain when resting. This condition, ischemic rest pain, is characterized by symptoms visible on the feet and toes. These include **ulcers**, loss of hair, and the change to red color when feet are suspended. Other symptoms include blue or purple markings on the legs, feet, and toes. The coloring is a sign that less oxygen is reaching these areas. Furthermore, black skin on the legs and feet is a sign of **gangrene** infection.

Risks

The risk factors for intermittent claudication include:

- High blood pressure.
- Total blood cholesterol over 240 mg/dL.
- Obesity (being extremely overweight).
- Diabetes.
- Tobacco products, such as smoking.
- Over 70 years of age (over 50 years of age for tobacco users or those with diabetes).
- Family history of peripheral artery disease, atherosclerosis, or intermittent claudication.

Diagnosis

If a person experiences symptoms of intermittent claudication, their doctor will review the patient's medical history and examine the person for signs of the condition. This examination includes checking for a lower pulse or the absence of a pulse behind the knee, on the ankle, foot, and groin.

The doctor may order an ankle-brachial index (ABI) test to determine whether arteries are blocked. This procedure will verify if the person has PAD and provides information on the severity of the condition. The ABI measures blood pressure in the arms and ankle. Readings are taken when the person is at rest and after exercising lightly by walking on a treadmill. The ABI index is found by dividing the ankle blood pressure by the pressure for the arm. An ABI below 0.90 in a person at rest is a sign of PAD.

The physician may also order a Doppler **ultrasound** examination to measure the flow of blood through the arteries. Cuffs are placed on four places on each leg. The doctor then moves an ultrasound probe over arteries in the foot. The probe detects signals (sound waves) from the artery. Testing can last from 20 minutes to an hour. The results will show the degree of PAD for the patient. The procedures are usually covered by medical insurance.

Treatment

Lifestyle changes are the primary form of treating intermittent claudication. Physicians advise people to quit smoking, exercise, and to follow the American Heart Association's healthy diet guidelines. Other suggestions may be to lower blood pressure and cholesterol levels.

The goal of treatment is to stop development of PAD. By exercising, eating a diet that includes fiber and low-fat foods, and not smoking, a person could also reverse the build-up that clogs arteries. After several months of this regimen, many people experience a lessening of leg pain. If pain continues, the doctor may prescribe medication. Surgery may be needed in some cases. In most cases, when treated properly, intermittent claudication can be controlled without pain so patients can live an active lifestyle.

Walking

Walking is frequently an important treatment for intermittent claudication. A person experiencing the pain of intermittent claudication may not feel like walking. However, walking can increase the capacity to exercise. Before starting an exercise program, the person should consult with consult with a doctor.

The physician reviews the patient's medical history, does a physical and may order an exercise **stress test** on a treadmill. The test shows how long a person walks before claudication starts. Information such as blood pressure is used to evaluate the person's ability to walk. The findings are also used to develop a medically supervised exercise program.

At the beginning, the treadmill is set to cause claudication symptoms in 3–5 minutes, according to the Vascular Disease Foundation. The person walks until pain is moderately severe. A rest period is scheduled after the person walks 8–10 minutes.

The person walks and rests, with the goal of walking for a total of 35 minutes. The person walks at least three times weekly. If a treadmill is not available, VDF recommends that people walk on a track. Generally, a person walking three times weekly will be able to walk longer after 3–12 months.

Medications

People diagnosed with PAD are at a high risk for a stroke and **heart attack**. Regularly taking **aspirin** may reduce this risk. Clopidogrel, a drug marketed as Plavix, has been shown to also reduce such risks. Other medications include angiotensin converting enzyme (ACE) inhibitors, beta-blockers, pentoxifylline, and cilostazol (selective PDE3 inhibitor).

A doctor may also prescribe cilostazol—sold under the name Pletal—which extends the distance people can walk without pain. One tablet is taken twice daily.

Surgical procedures

Surgical procedures may be necessary in cases where intermittent claudication is disabling. The person experiences pain when resting, has open sores that do not heal, or symptoms of gangrene like dying skin in the leg or foot.

Bypass surgery directs blood through a grafted blood vessel, bypassing the damaged artery. The grafted vessel is either a healthy artery or vein or an artificial vessel.

Angioplasty is a procedure to open blocked blood vessels. A catheter (tube) is inserted in the groin and moved to the artery. Then a tiny balloon is inflated to open the artery. Another angioplasty procedure involves the insertion of a stent, a metal device that keeps the vessel open.

Angioplasty is a minimally invasive procedure. Local **anesthesia** is used, and a person is able to resume normal activities within one to two days. The cost of angioplasty is less than one-half the cost of bypass surgery. A non-invasive procedure is not as risky as surgery. However, a bypass may be needed when multiple sections of blood vessels are blocked.

Once a person is diagnosed with intermittent claudication, health plans usually cover part of treatment costs.

Alternatives

Ginkgo biloba extract, an herbal remedy, has been used by people with intermittent claudication. The extract made from the dried leaves of the Gingko tree is thought to improve blood flow, allowing people to walk longer without pain.

However, herbal remedies are not regulated the U.S. Food and Drug Administration, and people should consult with their doctors before taking ginkgo. Furthermore, use of this remedy could interact adversely when taken with **vitamin E** and vitamin B_3, which are also used as alternative treatments, and some other medications.

WWW.BOOKBAZ.IR

KEY TERMS

Arthrosclerosis—A condition where fatty deposits cause the arteries to narrow.

Gangrene—The decay of tissue in the body; it is caused by an obstruction to the blood supply.

Prognosis

If untreated, advanced intermittent claudication can eventually restrict a person's mobility. In later stages, people feel pain when resting. The leg or foot may feel cold. In the extreme stage, the person might need a cane, walker, or wheelchair. There is more risk of gangrene developing, and **amputation** might be necessary. Diabetics face an increased risk of amputation. PAD also increases the risk of heart attacks and strokes.

Prevention

A healthy lifestyle is the best method for preventing intermittent claudication. Cigarette smokers should quit smoking. Regular exercise and a healthy diet may help reduce the risk of this condition. Maintaining healthy blood pressure and cholesterol levels may also help to prevent this condition.

The methods of preventing intermittent claudication are also the means for managing the risks associated with a diagnosis of PAD.

People can learn more about peripheral vascular disease through public education programs like the free Legs for Life screenings held at sites across the nation. The program, started by the Society of Interventional Radiology, features a free ABI testing.

Liz Swain

Intermittent explosive disorder

Definition

Intermittent explosive disorder (IED) is a mental disturbance that is characterized by specific and repeated episodes of violent and aggressive behavior that may involve harm to others or destruction of property. Throwing and breaking of objects are often part of the behavior. Often the anger and violence seen in such an individual reaches a point of uncontrollable rage. Such behavior seems out of context to the situation at hand during such outburst. Common signs of IED are temper tantrums, domestic **abuse**, and road rage. IED is sometimes grouped together as an impulse–control disorder with other such behavioral disorders such as kleptomania, pyromania, and pathological gambling.

A person must meet certain specific criteria to be diagnosed with IED:

- There must be several separate episodes of failure to restrain aggressive impulses that result in serious assaults against others or property destruction.

- The degree of aggression expressed must be out of proportion to any provocation or other stressor prior to the incidents.
- The behavior cannot be accounted for by another mental disorder, substance abuse, medication side effects, or such general medical conditions as epilepsy or head injuries.

Many psychiatrists do not place IED into a separate clinical category but consider it a symptom of other psychiatric and mental disorders. In many cases individuals diagnosed with IED do in fact have a dual psychiatric diagnosis. IED is frequently associated with mood and **anxiety disorders**, substance abuse and **eating disorders**, and narcissistic, paranoid, and antisocial **personality disorders**.

Demographics

With regard to sex and age group, the majority of individuals diagnosed with IED in the United States are adolescent and adult males. Women do experience IED and have reported it as part of **premenstrual syndrome** (PMS). IED may appear in childhood but is usually misdiagnosed as temper tantrums. Later in life, it often goes undiagnosed for years because it is a relatively rare condition.

According to researchers at the National Institutes of Health, in 2006, approximately 2.2 million persons in the United States (about 7.3% of the total population) met the criteria for IED, with a total of 11.5–16 million meeting the lifetime criteria for the disorder.

Description

People diagnosed with IED sometimes describe strong impulses to act aggressively prior to the specific incidents reported to the doctor and/or the police. They may experience racing thoughts or a heightened energy level during the aggressive episode, with **fatigue** and depression developing shortly afterward. Some report various physical sensations, including tightness in the chest, tingling sensations, increased energy, tremor, hearing echoes, irritability, or a feeling of pressure inside the head.

Many people diagnosed with IED appear to have general problems with anger or other impulsive behaviors between explosive episodes. Some are able to control aggressive impulses without acting on them while others act out in less destructive ways, such as screaming at someone rather than attacking them physically.

Causes and symptoms

Causes

As with other impulse–control disorders, the cause of IED has not been determined. Researchers disagree as to whether it is learned behavior (environmental in nature), the result of biochemical or neurological abnormalities (biological in nature), or a combination of factors. Some scientists have reported abnormally low levels of serotonin, a neurotransmitter that affects mood, in the cerebrospinal fluid of some anger–prone persons, but the relationship of this finding to IED is not clear. Generally, IED patients also have higher levels of the hormone testosterone in the systems. Similarly, some individuals diagnosed with IED have a medical history that includes migraine headaches, seizures, attention–deficit hyperactivity disorder, or developmental problems of various types, but it is not clear that these cause IED, as most persons with migraines, learning problems, or other neurological disorders do not develop IED.

Some psychiatrists who take a cognitive approach to mental disorders believe that IED results from rigid beliefs and a tendency to misinterpret other people's behavior in accordance with these beliefs. According to American psychologist Aaron Beck (1921–), a pioneer in the application of cognitive therapy to violence–prone individuals, most people diagnosed with IED believe that other people are basically hostile and untrustworthy, that physical force is the only way to obtain respect from others, and that life in general is a battlefield. Beck also identifies certain characteristic errors in thinking that go along with these beliefs:

- Personalizing. The person interprets others' behavior as directed specifically against him or her.
- Selective perception. The person notices only those features of situations or interactions that fit his or her negative view of the world rather than taking in all available information.
- Misinterpreting the motives of others. The person tends to see neutral or even friendly behavior as either malicious or manipulative.
- Denial. The person blames others for provoking his or her violence while denying or minimizing his or her own role in the fight or other outburst.

Symptoms

The symptoms that can precede episodes of IED, or can accompany the disorder, include:

- Rage.
- Increased energy.

WWW.BOOKBAZ.IR

- Tingling.
- Tremors.
- Palpitations.
- Irritability.
- Headache, or feeling of pressure in the head.
- Tightness in the chest.

Risks

People with increased risk of having IED may have these other characteristics:

- Substance abuse (more likely to have abused drugs or alcohol).
- Age (younger people are more prone to IED).
- Gender (men are more likely than women to have IED).
- Other mental health problems (people with other mental illnesses, such as anxiety attacks or depression, are more likely to also have IED).
- Previous physical abuse (people previously abused physically as children are at higher risk of IED).

Diagnosis

The diagnosis of IED is basically a diagnosis of exclusion, which means that the doctor will eliminate such other possibilities as neurological disorders, mood or substance abuse disorders, **anxiety** syndromes, and personality disorders before deciding that the patient meets the *DSM-5* criteria for IED. In addition to taking a history and performing a **physical examination** to rule out general medical conditions, the doctor may administer one or more psychiatric inventories or screeners to determine whether the person meets the criteria for other mental disorders.

In some cases the doctor may order imaging studies or refer the person to a neurologist to rule out brain tumors, traumatic injuries of the nervous system, **epilepsy**, or similar physical conditions.

Patients diagnosed with IED are also usually diagnosed with at least one other disorder, such as personality disorders, substance abuse, or neurological disorders.

Along with these other evaluations, the doctor will also investigate the personal and professional history of the patient. People with IED often have problems in school, keeping a job, and interpersonal relationships (including divorce), along with numerous automobile accidents and law enforcement crimes.

Treatment

Emergency room treatment

A person brought to a hospital emergency room by family members, police, or other emergency personnel after an explosive episode will be evaluated by a psychiatrist to see whether he or she can safely be released after any necessary medical treatment. If the patient appears to be a danger to him/herself or others, the person may be involuntarily committed for further treatment. In terms of legal issues, a doctor is required by law to notify the specific individuals as well as the police if the patient threatens to harm particular persons. In most states, the doctor is also required by law to report suspected abuse of children, the elderly, or other vulnerable family members.

The doctor will perform a thorough medical examination to determine whether the explosive outburst was related to substance abuse, withdrawal from drugs, head **trauma**, **delirium**, or other physical conditions. If the patient becomes assaultive inside the hospital, he or she may be placed in restraints or given a tranquilizer (usually either lorazepam [Ativan] or diazepam [Valium]), usually by injection. In addition to the physical examination, the doctor will obtain as detailed a history as possible from the family members or others who accompanied the patient.

Medications

Medications that have been shown to be beneficial in treating IED in nonemergency situations include lithium, carbamazepine (Tegretol), propranolol (Inderal), and such **selective serotonin reuptake inhibitors** as fluoxetine (Prozac) and sertraline (Zoloft). Adolescents diagnosed with IED have been reported to respond well to clozapine (Clozaril), a drug normally used to treat **schizophrenia** and other psychotic disorders.

Psychotherapy

Some persons with IED benefit from cognitive therapy in addition to medications, particularly if they are concerned about the impact of their disorder on their education, employment, or interpersonal relationships. Psychoanalytic approaches are not useful in treating IED.

Prognosis

The prognosis of IED depends on several factors that include the individual's socioeconomic status, the stability of his or her family, the values of the surrounding neighborhood, and his or her motivation to

KEY TERMS

Cognitive therapy—A form of short–term psychotherapy that focuses on changing people's patterns of emotional reaction by correcting distorted patterns of thinking and perception.

Delirium—An acute but temporary disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. Delirium may be caused by drug intoxication, high fever related to infection, head trauma, brain tumors, kidney or liver failure, or various metabolic disturbances.

Kleptomania—A mental disorder characterized by impulsive stealing.

Neurotransmitter—Any of a group of chemicals that transmit nerve impulses across the gap (synapse) between two nerve cells.

Pyromania—A mental disorder characterized by setting fires.

Serotonin—A neurotransmitter or brain chemical that is responsible for transporting nerve impulses.

change. As some patients age, the disorder tends to decrease in its severity. However, in others the disorder becomes chronic.

Prevention

There is not a clear way to prevent this disorder. It is difficult to diagnose until symptoms begin to appear. Since the causes of IED are not fully understood, preventive strategies should focus on treatment of young children (particularly boys) who may be at risk for IED before they enter adolescence. Teaching self–control skills at a young age is been shown helpful in controlling the disorder.

Intermittent fasting

Definition

Intermittent **fasting** (IF) is a name for a group of calorie restriction (CR) **diets** in which the dieter alternates between periods of fasting (usually consuming water or no-calorie beverages only) and non-fasting. IF is based on time periods rather than on meal plans, food lists, recipes, calorie counting, or similar features of most weight-loss diets. One common form of IF appears to be a two-day cycle in which 24 hours of fasting are followed by 24 hours of feeding. This pattern is alternately known as alternate-day fasting (ADF), every-other-day fasting (EOD), or every-other-day feeding (EODF). Other IF diets may divide each day into a period of fasting and a period of feeding, such as 20 hours of fasting/4 fours of feeding or 19 hours of fasting/5 hours of feeding. Another variation is to consume a very limited number of calories (usually 15–20% of normal intake) on fasting days rather than taking in no calories at all.

Description

Intermittent fasting as a dietary regimen appears to have originated with laboratory experiments on

WWW.BOOKBAZ.IR

animals (mice in most cases) in the 1940s, in which researchers discovered that calorie restriction (CR) in the form of intermittent fasting appeared to extend the animals' life spans. Calorie restriction without **malnutrition** has been shown to extend the median and maximum life spans in such different species as yeast, fish, and dogs as well as mice, but its effects in humans are not yet fully understood because of the length of the human life span in comparison to the life spans of other animals.

IF seems to be practiced primarily by bodybuilders and athletes in developed countries, who may combine it with food cycling regimens of various types. Food cycling refers to the practice followed by some weight trainers of reversing the proportions of fats and carbohydrates in the diet according to the phase of the training schedule—usually high carbohydrate/low fat on training days and low carbohydrate/high fat on rest days.

There is no single IF diet, but rather several different regimens. Some of the better-known IF regimens include 2 Meal, LeanGains, Fast-5, Eat Stop Eat, 5:2 Fast Diet, and the Warrior Diet.

2 Meal (IF Life)

The 2 Meal version of intermittent fasting has been popularized by Michael O'Donnell, a personal trainer and fitness coach who began to write about his approach in 2007 and refers to himself as "2 Meal Mike." The 2 Meal system, also called IF Life, is the easiest version of IF to tailor to an individual's preferences; O'Donnell describes it as "a simple way to eat less overall for weight loss." The "2 Meal" in the program's title refers to limiting one's eating to two meals a day. O'Donnell states that he rarely eats breakfast, has a late lunch, and then eats one other meal per day, usually in the early evening. Rather than specify an ideal length of time for fasting/feeding, O'Donnell notes that his own daily feeding "window" can vary from six to 10 hours in length. While he advises beginners to start with set times for meals so that they do not have too many variables to adjust, he emphasizes that "less is more" and that "many ways can work" for people to benefit from the 2 Meal approach.

O'Donnell's claims for his version of IF are modest. He notes that no one diet plan works for everyone, and that such factors as **insulin resistance**, general level of activity, choice of foods and total calorie consumption, amount of rest and sleep, and the presence of any metabolic disorders can affect the rate of weight loss and success in weight maintenance. His overall advice is to avoid making intermittent fasting unduly complicated—the focus should be on enjoying life rather than worrying about the diet.

LeanGains

LeanGains is an IF program devised and popularized by Martin Berkhan, a Swedish personal trainer and magazine writer who maintains a blog about his dietary recommendations. Berkhan, who holds an undergraduate degree in **public health** sciences and education, maintains that he became interested in IF when he found that the six-meals-a-day regimen often recommended for athletes did not work for him either physically or psychologically; in particular, he noticed that his life had started to revolve around food: "The constant meal preparing, the obsessiveness about eating the perfect meals at the right time, and the way I sometimes made excuses not to participate in social gatherings in order to meet my calorie and macronutrient goals for the day." He experimented with intermittent fasting, noted the range of IF patterns reported in the literature, and settled on one that worked for him and his bodybuilding clients.

Berkhan's version of IF is based on a 16/8 daily pattern of fasting/eating rather than an alternate-day pattern. He and most of his clients eat three meals during the eight-hour feeding window: a pre-workout meal and two post-workout meals. Unlike O'Donnell, Berkhan has strong convictions about the proper balance of nutrients in the pre- and post-workout meals, stating that the pre-workout meal should be light (about 500 calories), with equal amounts of carbohydrates and proteins, as well as "some fat for taste." A typical pre-workout meal for Berkhan might include 5 oz. (142 g) of lean meat, a potato or other vegetable, and a large apple. The post-workout meals should account for 80% of the day's calorie intake and be high in carbohydrates, moderate in protein, and low in fat. Berkhan states that he usually eats one post-workout meal immediately after the workout and the second meal about an hour before bedtime. Like most proponents of intermittent fasting, Berkhan notes that limiting one's total calorie consumption is still necessary to lose weight, and that IF will not work if people regard the eating window as an excuse to binge.

Fast-5

The Fast-5 approach to intermittent fasting was devised in the early 2000s by a physician named Bert Herring and his wife, also a physician. The Fast-5 program resembles O'Donnell's 2 Meal approach in that it is relatively flexible. It is based on a 19/5 daily pattern of fasting/eating, with all eating to be done within the five-hour window. During that five-hour

period, the dieter is to eat as much as they want, so long as they are truly hungry. No liquids containing calories are to be consumed during the 19-hour fasting period, although the dieter may drink as much water or other calorie-free beverages as desired. The Herrings emphasize that any period of five consecutive hours is fine to use as the eating window, so that users can identify a time frame that works for them.

The Herrings outline two ways to start the Fast-5 program: a "cold turkey" approach, in which the dieter simply waits to eat until the chosen five-hour window, or a gradual adjustment approach, in which the timing of the eating window is pushed back by half an hour or an hour every day or every few days until the person reaches the desired time setting for the window. With regard to choice of foods, the Herrings recommend a variety of fruits and vegetables containing fiber; a variety of protein sources that include fish, eggs, and meat; and nuts or sunflower seeds—in short, "a balance of carbohydrate, fats, and protein."

The Herrings advise that people may not notice weight loss until they have used the Fast-5 approach for three or four weeks, and that they may find they are losing inches from the waistline before their scale registers a loss in weight. The Herrings refer to the initial three weeks as the adjustment period, and maintain that dieters using the Fast-5 approach should begin to lose about a pound per week after a month or longer on the program.

Eat Stop Eat

Eat Stop Eat is a version of intermittent fasting popularized by Brad Pilon, who is the author of two e-books, *Eat Stop Eat* (in two versions, one for men and one for women) and *The Zen of Nutrition*. Pilon's approach to IF consists of one or two 24-hour fasts per week, the day(s) chosen by the user. Pilon recommends that people choose days when they are not too busy. **Exercise** should be done when energy levels are highest, which will usually be toward the beginning of the fast. The fast usually begins on the evening before the fast day and ends 24 hours later on the following evening. During the fast, the dieter may drink any fluid that does not contain calories: coffee, unsweetened tea, water, club soda, diet soft drinks, and the like.

Warrior diet

The Warrior diet is sometimes loosely grouped together with other IF regimens because it is based on a daily cycle of overeating and undereating, but it differs from intermittent fasting in a number of important respects. Designed by Ori Hofmekler (1952–), a former member of the Israeli Defense Force (IDF), the Warrior diet is a total workout, fitness, and **nutrition** program; it is not primarily a weight-loss program. Second, the undereating phase of the Warrior diet is not really a fast; the dieter is allowed to consume light snacks of raw fruits or vegetables or a light protein food like yogurt for the 10–18 hours a day that constitute the undereating period. In addition, Hofmekler maintains that people do not need to count calories during the overeating period; they can basically eat as much food as they wish. This advice is quite different from that of most IF proponents, who state that the eating window in their various plans is not an excuse to binge, and that calories do count if the user wishes to lose weight. Third, the Warrior diet is accompanied by an intense and rigorous exercise program based on whole-body workouts that may last as long as 45 minutes.

The Warrior diet also differs from other IF plans in its rules about cooking and eating. Like Berkhan, Hofmekler believes in food cycling; dieters should alternate between high-fat and high-carbohydrate days in order to maximize the body's fat burning during exercise. Hofmekler advises people to avoid storing foods in plastic containers or purchasing foods wrapped or contained in plastic. He believes that only bottled water should be used for drinking and cooking and that supermarket foods contain "estrogenic compounds." Hofmekler's preoccupation with estrogens in the environment has no parallel in other IF regimens. Last, Hofmekler has a website called Defense Nutrition, through which he markets a number of dietary supplements intended to help the body burn fat, detoxify, rid itself of estrogenic compounds, and maintain a normal hormonal balance. These products are quite expensive—$170 for a 30-day "protein support kit" as of 2012—which again sets the Warrior diet apart from other IF regimens.

Purpose

The purpose of IF is to help otherwise healthy adults lose weight at a slow but steady rate while choosing foods that appeal to them and an overall fasting/feeding pattern that works for them as individuals. Berkhan also maintains that IF can be used by bodybuilders to increase lean muscle mass and/or decrease the proportion of body fat.

In addition to a healthful rate of weight loss, proponents of IF maintain that it offers several additional benefits:

- The calorie restriction that occurs with IF has been shown to reduce inflammation, lower blood pressure and blood glucose levels, lower triglyceride and total

WWW.BOOKBAZ.IR

cholesterol levels, and reduce body fat while sparing lean muscle tissue.

- The flexibility of IF relieves people of the emotional burdens of calorie counting, obsessions with meal planning and preparation, and feelings of deprivation related to "forbidden" foods. Most proponents of IF encourage people to have something they consider a pleasure or a "treat" during the feeding window, which can lead to better adherence of the plan.
- IF also allows people to adjust the timing of their feeding window for eating out, business trips, social events, and similar occasions, thus easing concerns about social isolation.
- Many users report increased mental energy and ability to concentrate because they are not constantly preoccupied with food or food preparation.
- Other users report less interest in sweets or processed foods and heightened enjoyment of natural flavors in foods.
- IF can easily accommodate people with food allergies who may need to avoid certain foods often included in conventional weight loss plans.
- IF is easy on the food budget because users do not have to spend money on exotic foods or cooking equipment, dietary supplements (with the exception of the Warrior diet), diet books, membership in a diet program, or similar expenses. They also usually find that they save money on food because they are eating less.

Risks

Although Berkhan claims that he has clients with diabetes who have successfully used his approach to IF, most IF proponents state that their programs are intended for otherwise healthy adults who need to lose weight; they are not intended for children or adolescents who are still growing, pregnant or lactating women, or anyone with a chronic disorder, including diabetes.

There are many difficulties to following an IF regimen. People with a history of **eating disorders**, **stress**, or **anxiety disorders** may find that the restrictions of IF can worsen these conditions. The diets can be hard to follow for an extended period of time, especially for people who live with others who do not practice IF. Some researchers are concerned that IF promotes weight cycling or yo-yo dieting, due to the extremes between eating nothing and eating anything.

Repeated fasting can result in nutrient deficiencies. People may feel fatigued during the fasting periods. Anyone interested in IF should first consult with their physician to help avoid any complications.

KEY TERMS

Calorie restriction (CR)—The limitation of daily calorie intake below a person or animal's previous unrestricted level, most often by 10–25%. Some researchers believe that CR could extend the human life span, as it appears to have that effect in some other species.

Circadian rhythm—Any biological rhythm that originates within an organism and has a time pattern of about 24 hours. In humans, the term is often used to describe the sleep/wake cycle.

Insulin resistance—A state or condition in which a person's body tissues have a lowered level of response to insulin, a hormone secreted by the pancreas that helps to regulate the level of glucose (sugar) in the body.

Weight cycling—A recurring pattern of losing and then gaining weight.

Window—The term used in intermittent fasting to refer to the time period when eating is allowed. It is also called the eating window.

Research and general acceptance

Relatively little scientific research has been done on IF in humans, possibly because there are a number of different fasting/feeding patterns that identify themselves as intermittent fasting. Many of the writers in the field are personal trainers or bodybuilders rather than research scientists. The Academy of Nutrition and Dietetics states in March 2014 that although animal studies and early human studies show positive effects, additional studies in humans are needed. Fasting for at least 16 hours is generally easier for elite athletes to maintain, yet the organization's review also stated that competitive athletes should work with a coach, athletic trainer, and a registered dietitian nutritionist when controlling weight and body composition. Further, people who are not elite athletes may not be best served by IF. Problems such as **dizziness**, **fatigue**, or nausea can accompany long periods of fasting. And people who are not in the same shape as competitive athletes may not be able to perform regular physical workouts while restricting food intake.

There are only a handful of published studies on IF in humans compared to those that used mice models. One study reported that IF does not appear to affect the metabolism of different nutrients in healthy subjects compared to control subjects on a normal diet.

A British study stated in 2011 that IF is at least as effective as a daily calorie-restricted diet in weight management and insulin sensitivity in overweight women. A team of Israeli investigators suggested in 2010 that the beneficial effects reported by adults using an IF feeding regimen may be due in part to the way in which IF resets the body's circadian rhythm. Most registered dietitians maintain that much more research needs to be done on IF in humans to gain a clearer understanding of its effects on the human body or the **aging** process, and the metabolic pathways or other reasons for those beneficial effects.

A 2014 study on the effects of IF compared with daily calorie restriction on type 2 diabetes control found that study subjects who used calorie restriction actually lost more weight than those who used IF and alternate day fasting. Loss of fat and reductions in fasting insulin and insulin resistance were similar for fasting and calorie restriction diet methods. A clinical trial was planned, but not yet begun, in summer 2014 to evaluate the effects of IF on people who are eating a Mediterranean or Western diet. A few other studies had been concluded as of summer 2014, but results were not yet published.

Internet addiction disorder

Definition

Internet **addiction** disorder (IAD) refers to the problematic use of the Internet, including the various aspects of its technology, such as electronic mail (email) and the World Wide Web. It is also known as problematic computer use, pathological computer use, and Internet overuse. Internet addiction disorder is

WWW.BOOKBAZ.IR

not listed in the mental health professional's handbook, the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), possibly because the name of the disorder was originally proposed as a satirical spoof by a New York City psychiatrist in 1995. Internet addiction has, however, been formally recognized as a disorder by the American Psychological Association.

Although some psychiatrists have recommended adding diagnostic criteria for IAD to the fifth edition of the *DSM*, known as *DSM-5*, the disorder was not included in the manual. Much of the debate focuses on whether IAD is a distinctive disorder or whether it is simply an instance of a new technology being used to support other addictions. For example, there are gambling casinos on the Internet that could reinforce a person's preexisting gambling addiction. Similarly, someone addicted to shopping could transfer their addiction from the local mall to online stores or such auction sites as eBay. Persons addicted to certain forms of sexual behavior can visit pornography sites on the Internet or use chat rooms as a way to meet others who might be willing to participate in those forms of behavior. The consensus seems to be that most, if not all, persons with IAD fall into established diagnostic categories.

Demographics

In the past, people reported to have an Internet addiction disorder were stereotyped as young, introverted, socially awkward, computer-oriented males. While this stereotype may have been true in the past, the availability of computers and the increased ease of access to the Internet are quickly challenging this notion. As a result, problematic Internet use can be found worldwide in any age group, social class, racial or ethnic group, level of education and income, and gender. One researcher in the Boston area estimates that between 6% and 10% of people who surf the Web have some type of Internet dependency; and the American Academy of Pediatrics (AAP) estimates that between 8% and 12% of American children and adolescents have IAD. One reason for ongoing debate about the demographics of IAD, however, is that the disorder appears to have subtypes with different subpopulations.

Description

In some respects, addictive use of the Internet resembles other so-called process addictions, in which a person is addicted to an activity or behavior (including gambling, shopping, or certain sexual behaviors) rather than a substance (mood-altering drugs, tobacco, food, etc.). People who develop problems with their Internet use may start off using the Internet on a casual basis and then progress to using the technology in dysfunctional ways.

Some researchers maintain that there are several distinctive types of IAD rather than a single disorder:

- Online gaming. There are reported instances of people falling dead from exhaustion after several days of uninterrupted Internet gaming, although no one knows for certain how often such extreme cases arise.
- Internet pornography. This is a large subgroup; over 60% of people seeking treatment for IAD claim they are involved with online sexual activities that they consider inappropriate. People in this subgroup are more likely than others with IAD to have a substance abuse disorder.
- Online shopping. Most researchers consider online shopping addiction to be an extension of compulsive shopping in brick-and-mortar stores rather than a distinctive disorder, although some consider addiction to online auction sites like eBay to be a separate subtype.
- Email and texting.
- Social media. Social media is a general term for both Web-based and mobile technologies that facilitate social (rather than business or academic) interaction online. It was estimated that as of 2014, about 74% of all online adults in the United States use social networking sites.
- Blogging. Blogging is a word derived from "weblog," a personal website maintained by an individual or group, with regular additions of commentary, descriptions of events, or personal videos. Most blogs are set up to allow comments from readers, which make it a form of social media in many cases.

Many people believe that spending large amounts of time on the Internet is a core feature of the disorder. The amount of time by itself, however, is not as important a factor as the ways in which the person's Internet use is interfering with their daily functioning. Use of the Internet may interfere with social life, school work, or job-related tasks at work. In addition, cases have been reported of persons entering Internet chat rooms for people with serious illnesses or disorders, and pretending to be a patient with that disorder in order to get attention or sympathy. Treatment options often mirror those for other addictions. Although only a limited amount of research has been done on this

disorder, the treatments that have been used appear to be effective.

One newer concern about IAD is the growing use of portable or handheld devices that can access the Internet, such as tablet PCs, smartphones, and other devices connected to the Internet via wireless networks. In 2008, mobile access to the Internet exceeded desktop computer-based access for the first time, and the popularity of mobile devices continues to rise. While these devices have much to offer users who need Web access in situations where a desktop computer is unavailable, they also allow others to spend excessive time on the Internet outside their houses or offices.

Risk factors

The most commonly identified risk factors for IAD include age between 12 and 25; pre-existing **mood disorders**; diagnosis of **attention deficit hyperactivity disorder (ADHD)** or **obsessive-compulsive disorder** (OCD); a history of process addiction; and a history of drug or alcohol abuse.

Gender is a risk factor for some forms of IAD. Most online gaming and pornography addicts are males, while women are at slightly greater risk for online shopping addiction. There is some evidence that male online shopping addicts are often unrecognized, because they tend to purchase different types of items (e.g., hardware, automotive equipment, and electronic devices or gadgets) from those favored by women (e.g., clothing, jewelry, and cosmetics).

Causes and symptoms

Causes

No one knows what causes a person to be addicted to the Internet, but there are several factors that have been proposed as contributing to Internet addiction. One theory concerns the mood-altering potential of behaviors related to process addictions. Just as a person addicted to shopping may feel a "rush" or pleasurable change in mood from the series of actions related to a spending spree—checking one's credit cards, driving to the mall, going into one's favorite store, etc.—the person with an Internet addiction may feel a similar rush from booting up their computer and going to their favorite websites. In other words, some researchers think that there are chemical changes that occur in the body when someone is engaging in an addictive behavior. From a biological standpoint, there may be a combination of genes that make a person more susceptible to addictive behaviors, just as researchers have located genes that affect a person's susceptibility to alcohol.

In addition to having features of a process addiction, Internet use might be reinforced by pleasurable thoughts and feelings that occur while the person is using the Internet. Although researchers in the field of addiction studies question the concept of an addictive personality as such, it is possible that someone who has one addiction may be prone to become addicted to other substances or activities, including Internet use. People with such other mental disorders or symptoms as depression, feelings of **isolation**, **stress**, or **anxiety**, may self-medicate by using the Internet in the same way that some people use alcohol or drugs of abuse to self-medicate the symptoms of their mental disorder. Still another theory is that Internet overuse is akin to dissociation in that it allows a person to compartmentalize difficulties in their present life and escape from reality into an online virtual world.

From a social or interpersonal standpoint, there may be familial factors prompting use of the Internet. For example, a person might "surf the Web" to escape family conflict. Another possibility is that social or peer dynamics might prompt excessive Internet use. Some affected persons may lack the social skills that would enable them to meet people in person rather than online. Peer behavior might also encourage Internet use if all of one's friends are using it. Modeling may play a role-users can witness and experience how others engage in Internet use and then replicate that behavior. The interactive aspects of the Internet, such as chat rooms, email, and interactive games like Multi-User Dungeons and Dragons (MUDS), seem to be more likely to lead to Internet addiction than purely solitary web surfing.

Symptoms

The most noticeable symptom of Internet addiction is excessive time devoted to Internet use. A person might have difficulty cutting down on his or her online time even when they are threatened with poor grades or loss of a job. There have been cases reported of college students failing courses because they would not take time off from Internet use to attend classes. Other symptoms of addiction may include lack of sleep; **fatigue**; declining grades or poor job performance; apathy; and racing thoughts. There may also be a decreased investment in social relationships and activities. A person may lie about how much time was spent online or deny that they have a problem. They may be irritable when offline or angry toward anyone who questions their time on the Internet.

Some pediatricians attribute an increase in depression among adolescents to the widespread popularity of social media. The term Facebook depression has

WWW.BOOKBAZ.IR

KEY TERMS

Blogging—Creating and maintaining an online personal website, in most cases allowing readers to add comments. The term comes from the word weblog, or online diary.

Dissociation—A condition in which a person's thoughts, emotions, sensations, or memories become compartmentalized, usually as a result of a severe emotional trauma.

Facebook depression—A term used to describe an adolescent mood disorder associated with low self-esteem and depressed mood triggered by excessive concern with online social media.

Process addiction—A term used to describe addiction to an activity or behavior rather than a mood-altering chemical. It is also known as behavioral addiction or non-substance-related addiction.

Social media—A general term for both Web-based and mobile technologies that facilitate social (as distinct from commercial or academic) interaction online.

been coined to describe the low self-esteem and mood disorders among some vulnerable adolescents induced by spending hours on Facebook and similar social networking sites. The researchers attribute Facebook depression to the way in which the medium facilitates constant comparisons of the self to other, presumably more popular, peers, and the common practice of posting negative or sarcastic comments on someone else's Facebook page.

Diagnosis

IAD was not added as an official diagnosis to the *DSM-5*. The following is a set of criteria for Internet addiction that has been proposed by addiction researchers. The criteria are based on the diagnostic standards for pathological gambling.

The patient must meet all of the following criteria:

- Preoccupation with the Internet (thinks about previous online activity or is anticipating the next online session).
- The need to spend longer and longer periods of time online in order to feel satisfied.
- Unsuccessful efforts to control, cut back, or stop Internet use.
- Restlessness, moodiness, depression, or irritability when attempting to cut down or stop Internet use.
- Repeatedly staying online longer than originally intended.

The person must meet at least one of the following criteria:

- Jeopardized or risked the loss of a significant relationship, job, educational or career opportunity because of Internet use.
- Lied to family members, a therapist, or others to conceal the extent of involvement with the Internet.
- Uses the Internet as a way of escaping from problems or of relieving an unpleasant mood (such as feelings of helplessness, guilt, anxiety, or depression).

Examination

There are no physical symptoms unique to IAD that can be detected during a standard **physical examination**.

Tests

There are no laboratory or imaging tests that can detect IAD. A set of self-tests for such specific problems as online pornography, online gaming, online auction addiction, online gambling, and general Internet addiction are available at http://www.netaddiction.com.

Two psychological inventories administered by mental health professionals, the Internet Addiction Test (IAT) and the Internet-Related Problem Scale (IRPS) were still undergoing clinical evaluation as of 2011.

Treatment

Traditional

Since Internet addiction disorder is a relatively new phenomenon, there is little research on the effectiveness of treatment procedures. It may be unrealistic to have a person completely end all Internet use. As society becomes more and more dependent on computers for business transactions, educational programs, entertainment, and access to information as well as interpersonal communication, it will be difficult for a computer-literate person to avoid using the Internet. Learning how to use the Internet in moderation is often the main objective in therapy, in a way analogous to the way that people with **eating disorders** need to come to terms with food. Many of the procedures that have been used to treat Internet addiction have been modeled after other addiction treatment programs and support groups, particularly 12-step groups.

Psychological interventions may include such approaches as changing the environment to alter associations that have been made with Internet use, or decrease the reinforcement received from excessive Internet use. Psychological interventions such as **cognitive-behavioral therapy** may also help the person identify thoughts and feelings that trigger their use of the Internet. Interpersonal interventions may include such approaches as social skills training or coaching in communication skills. Family and couple therapy may be indicated if the user is turning to the Internet to escape from problems in these areas of life. There is also a residential treatment program called ReSTART, which opened in the Pacific Northwest in 2009. The on-site program lasts 45 days and includes intensive individualized assessment as well as individual and **group therapy**.

Relapsing into an addictive behavior is common for anyone dealing with addiction disorders. Recognizing and preparing for relapse is often a part of the treatment process. Identifying situations that would trigger excessive Internet use and generating ways to deal with these situations can greatly reduce the possibility of total relapse. One option that works for some people is the installation of individualized content-control software on their computer; the software can be customized to block access to the types of websites that are most problematic for that person.

Drugs

If a person's IAD has a biological dimension, then medication such as an antidepressant or antianxiety drug may help him or her with these aspects of the addiction. There were no medications as of 2014 that specifically targeted IAD. One clinical trial completed in 2008 of escitalopram (Lexapro), an SSRI antidepressant, as a treatment for IAD found no difference between subjects who took the drug and those given a placebo. There were no new clinical trials for treatments for IAD as of 2014.

Prognosis

Although extensive studies have not yet been done, treatment appears to be effective in maintaining and changing the behavior of people drawn to excessive use of the Internet. If the disorder is left untreated, the person may experience an increased amount of conflict in his or her relationships. Excessive Internet use may jeopardize a person's employment or academic standing. In addition, such physical problems as fatigue, **carpal tunnel syndrome**, back **pain**, and eyestrain may develop.

Prevention

If a person knows that he or she has difficulty with other forms of addictive behavior, they should be cautious in exploring the types of applications that are used on the Internet. In addition, it is important for people to engage in social activities outside the Internet. One recommendation for parents of adolescents is to teach them about the proper uses and limitations of Facebook and other social networking sites as well as showing them how to make friends in everyday life. Finally, mental health workers should investigate ways to participate in the implementation of new technology rather than waiting for its aftereffects.

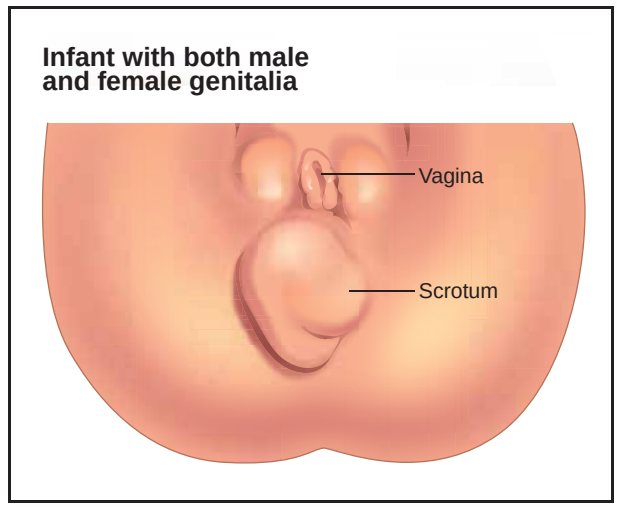
Intersex states

Definition

Intersex states are conditions where a newborn's sex organs (genitals) look unusual, making it impossible to identify the sex of the baby from its outward appearance.

Description

All developing babies start out with external sex organs that look female. If the baby is male, the internal sex organs mature and begin to produce the male hormone testosterone. If the hormones reach the tissues correctly, the external genitals that looked female change into the scrotum and penis. Sometimes, the genetic sex (as indicated by chromosomes) may not match the appearance of the external sex organs.



An illustration depicting an infant born with both male and female genitalia. Such a condition can make identification of gender impossible from outward appearance. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

About 1 in every 2,000 births results in a baby whose sex organs look unusual.

Patients with intersex states can be classified as a true hermaphrodite, a female pseudohermaphrodite, or a male pseudohermaphrodite. This is determined by examining the internal and external structures of the child.

A true hermaphrodite is born with both ovaries and testicles. They also have mixed male and female external genitals. This condition is extremely rare.

A female pseudohermaphrodite is a genetic female. However, the external sex organs have been masculinized and look like a penis. This may occur if the mother takes the hormone progesterone to prevent a miscarriage, but more often it is caused by an overproduction of certain hormones.

A male pseudohermaphrodite is a genetic male. However, the external sex organs fail to develop normally. Intersex males may have testes and a female-like vulva, or a very small penis.

Causes and symptoms

Any abnormality in chromosomes or sex hormones, or in the unborn baby's response to the hormones, can lead to an intersex state in a newborn.

Intersex states may also be caused by a condition called congenital adrenal hyperplasia, which occurs in about 1 out of every 5,000 newborns. This disease

KEY TERMS

Chromosomes—Spaghetti-like structures located within the nucleus (or central portion) of each cell. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

blocks the baby's metabolism and can cause a range of symptoms, including abnormal genitals.

Diagnosis

When doctors are uncertain about a newborn's sex, a specialist in infant hormonal problems is consulted as soon as possible. Ultrasound can locate a uterus behind the bladder and can determine if there is a cervix or uterine canal. Blood tests can check the levels of sex hormones in the baby's blood, and chromosome analysis (called karyotyping) can determine sex. Explorative surgery or a biopsy of reproductive tissue may be necessary. Only after thorough testing can a correct diagnosis and determination of sex be made.

Treatment

Treatment of intersex states is controversial. Traditional treatment assigns sex according to test results, the potential for the child to identify with a sex, and the ease of genital surgery to make the organs look more normal. Treatment may then include reconstructive surgery followed by hormone therapy. Babies born with congenital adrenal hyperplasia can be treated with cortisone-type drugs and sometimes surgery.

Counseling should be given to the entire family of an intersex newborn. Families should explore all available medical and surgical options. Counseling should also be provided to the child when he or she is old enough.

Prognosis

Since the mid-1950s, doctors have typically assigned a sex to an intersex infant based on how easy reconstructive surgery would be. The American Academy of Pediatrics states that children with these types of genitals can be raised successfully as members of either sex, and recommends surgery within the first 15 months of life.

Some people are critical of this approach, including intersex adults who were operated on as children. The remolded genitals do not function sexually and can be the source of lifelong pain. They suggest that surgery be delayed until the patient can make informed choices about surgery and intervention.

Interstitial microwave thermal therapy

Definition

Interstitial microwave thermal therapy is a type of hyperthermia treatment for cancer, in which heat produced by microwaves (a non-ionizing form of radiation) is used in conjunction with other cancer treatments, such as radiation or **chemotherapy**, to kill cancer cells associated with tumors located deep within the body.

Purpose

The purpose of interstitial microwave thermal therapy is to damage and kill cancer cells associated with tumors that are deep within the body. Interstitial microwave therapy is a type of hyperthermia cancer treatment procedure (also called thermal therapy or thermotherapy) in which body tissue and the cancerous tumor are exposed to high temperatures (up to 113°F [45°C]). Hyperthermia kills cancer cells with usually only minimal injury to normal tissues by damaging proteins and structures within the cells. Thermal therapy is usually used with other forms of cancer therapy, such as radiation and chemotherapy. The increased temperatures may make some cancer cells more sensitive to radiation or may harm some cancer cells that radiation cannot damage.

WWW.BOOKBAZ.IR

Precautions

If a patient has become insensitive to **pain** due to disease, radiation, surgery, anesthetics, or other conditions, hyperthermia treatment cannot be used to treat tumors. The excessive heating of normal surrounding tissue is prevented by normal blood perfusion, so hyperthermia should not be used in patients with known circulatory problems in the heated areas or in patients who are taking vasoconstrictive drugs.

Description

Interstitial microwave thermal therapy is used to treat tumors that are deep within the body, such as brain, cervical, breast, prostate, and neck tumors. This technique allows the tumor to be heated to higher temperatures than external thermal therapy techniques allow. Probes or needles are inserted into the tumor, guided by the use of imaging techniques, such as **ultrasound**, to make sure that the probe is properly located within the tumor. A new type of microwave generator includes electronic phase control that allows the operator to electronically direct and shape the pattern of hyperthermia treatments based on the positioning the microwave antennae array that is used in treating the tumor. The treatment pattern can be electronically targeted on the tumor position, shape, and size.

Tissues are heated as the electromagnetic energy produced by the microwave treatment results in heating through molecular excitation. This energy is dissipated in normal living tissue by the blood that perfuses through the tissue. However, since large solid malignant tumors have less blood perfusion than the surrounding normal tissue, for a given absorbed thermal dose, the tumor reaches a higher temperature than the normal tissue. Tumors present within normal tissue will be preferentially heated and will reach higher temperatures than the surrounding tissue.

As cancerous tumors grow rapidly, their need for blood quickly begins to exceed the available blood supply, and major portions of the tumors become blood-starved. These blood-starved tumors are resistant to both radiation and chemotherapy. Chemotherapy drugs carried through the blood cannot effectively penetrate tumors that have poor blood flow. Poor blood flow also means that the tumors are oxygen-starved (hypoxic), making it difficult for **radiation therapy** to make the oxygen radicals that are needed to destroy the DNA of cancer cells. Hypoxic cancer cells, which are an especially dangerous type of cancer, for they have a tendency to metastasize and spread the cancer to other parts of the body, are three times more resistant to ionizing radiation than are normal cells.

When the tumor is heated to **fever** levels through the use of microwave thermal therapy, its blood vessels expand so that more blood can flow into the tumor in order to carry away the excess heat. With the increased blood flow, more blood-borne chemotherapy drugs can be carried into the tumor. Blood is also the source of oxygen for tumors, so with increased blood flow due to the thermal therapy, radiation therapy can form the necessary oxygen radicals to kill the cancer cells. The increased temperature also acts as a drug activator, accelerating chemical reactions and pulling increased oxygen molecules into the tumor tissue for chemical reactions with the chemotherapy drug. **Hypothermia** also enhances the effectiveness of chemotherapy drugs encapsulated in liposomes, increasing the penetration of the drug into the tumor.

When tumors are heated to higher temperatures for at least an hour, the tumors in some cases have been shown to decrease in size and to exhibit **necrosis** (death of the tumor cells). Therefore, hyperthermia by itself also tends to shrink tumors, often dramatically, due to the collapse of dead cancer cells, making it easier to remove the tumor by surgical techniques. For tumors of the head and neck, a smaller tumor due to hyperthermia treatment may reduce the disfiguration associated with surgical removal of the tumor.

Hyperthermia is being studied as a means of enhancing **gene therapy** by acting as an activator to turn on new biological therapies, and by speeding up gene production by thousands of times. In addition, hyperthermia is used as an essential tool to turn on anti-tumor vaccines that are based on heat shock proteins. Hyperthermia has been shown to prevent a cancererous tumor from growing new blood vessels to expand its blood supply. With regards to quality of life, hyperthermia lessens pain and stimulates the immune system, thus helping patients recover from toxic cancer therapies such as ionizing radiation and chemotherapy. Even in patients with terminal cancer, hyperthermia can provide benefits through the alleviation of bleeding, pain, and infection.

The use of hyperthermia alone and in conjunction with radiation therapy has been approved by the U.S. Food and Drug Administration for the treatment of advanced, recurrent, and persistent tumors, upon authorization of a licensed practitioner. When used with radiation, the treatment regimen usually consists of 10 hyperthermia treatments delivered twice a week, at 72 hour intervals. The prescribed radiation is administered within 30 minutes of the hyperthermia

KEY TERMS

Blood perfusion—A physiological term that refers to the process of nutritive delivery of arterial blood to a capillary bed in the biological tissue.

Hyperthermia therapy—A type of treatment in which body tissue is exposed to high temperatures to damage and kill cancer cells or to make cancer cells more sensitive to the effects of radiation and certain anticancer drugs.

Non-ionizing radiation—Rays of energy that move in long, slow wave patterns and do not penetrate cells.

Ionizing radiation—Any electromagnetic or particulate radiation capable of producing ions, directly or indirectly, in its passage through matter.

treatment. During each heat treatment, the temperature within the tumor is usually maintained at 108.5°F (42.5°C) for 60 minutes. The use of hyperthermia in conjunction with chemotherapy is presently investigational in the United States.

The effectiveness of treatment is related to the temperature achieved during the treatment process, the length of the treatment, and cell and tissue characteristics. The temperature within the tumor must be monitored to ensure that the appropriate temperature is achieved, but not exceeded, in the treatment area. Monitoring is accomplished by inserting small needles or tubes with small thermometers into the treatment area. Imaging techniques such as computed tomography (CT) are used to make sure that the temperature probes are positioned appropriately.

Preparation

The safety and effectiveness of hyperthermia treatment is dependent on careful placement of the temperature probes and careful monitoring of tissue temperatures during treatment.

Aftercare

During the treatment period, which may last for weeks, the patient must be instructed in proper care of implanted catheters and temperature probe sites to avoid the risk of infection.

Risks

Excessive heating of normal tissues may result in areas of thermal aseptic necrosis that will require medical care. The electromagnetic radiation from the microwave equipment can interfere with electronic devices such as cardiac **pacemakers** or other implanted electronic devices. Thermal treatment of tumors in the neck or head may result in inadvertent heating of thermoregulatory centers in the brain stem, thus resulting in overheating of the body, beyond levels that the patient can tolerate. Metallic implants, such as joint protheses or dental braces may become excessively and preferentially overheated and adversely affect the patient.

Results

The effectiveness of interstitial microwave thermal therapy varies among cancer patients. For example, studies have shown in Phase III clinical trials, when hyperthermia was used with ionizing radiation treatment, that the following treatment improvements were seen, as compared to the use of ionizing radiation therapy alone:

- complete response for recurrent breast cancer increased from 38–60%
- 2-year survival for globlastoma (brain cancer) increased from 15–31%
- complete response for advanced cervical cancer increased from 57–83%

Known side effects of hypothermia are associated with direct effects of heat on tissues and indirect effects of tumor necrosis. These side effects, as determined in various medical studies, include:

- surface burns and blistering in the area of application of heat by the microwave applicators; experienced in about 10% of the tumor sites studied.
- localized and temporary pain in the area of and during the delivery of the heat by the microwave applicators; experienced in about 8% of the tumor sites studied.
- ulceration from rapid tumor necrosis following successful hyperthermia treatment, resulting in fever from toxemia and patient discomfort through drainage and bleeding; experienced in about 4% of the tumor sites studied.
- local and systematic (rarely) infections from placement of the temperature probes and from ulceration related to tumor necrosis; experienced in about 2% of the tumor sites studied.

WWW.BOOKBAZ.IR

Abnormal results

Hyperthermia has the potential for producing the following adverse reactions as a result of exposure to electromagnetic radiation:

- cataracts
- permanent or temporary male sterility
- exacerbation of existing diseases due to additional systemic stress
- enhanced drug activity
- thermal stress

Intestinal obstructions

Definition

Intestinal obstructions, sometimes also called bowel obstructions, refers to the partial or complete mechanical or non–mechanical blockages of fluids or foods of the small or large intestine (which includes the colon, cecum, and rectum). When such obstructions occur, they can lead to reduced or blocked passage of digested materials through the intestines. They are often caused by intestinal **adhesions**, hernias, or tumors.

Demographics

The disorder occurs in people of all ages, genders, and ethnic backgrounds.

Description

There are two types of intestinal obstructions, mechanical and non–mechanical. Mechanical obstructions occur because the bowel (intestines) is physically blocked and its contents cannot get past the obstruction. Mechanical obstructions can occur for several reasons. Sometimes the bowel twists on itself (volvulus) or telescopes into itself (**intussusception**). Mechanical obstruction can also result from hernias, impacted feces, abnormal tissue growth, the presence of foreign bodies in the intestines (including **gallstones**), or inflammatory bowel disease (Crohn's disease). Non–mechanical obstruction, called **ileus**, occurs because the wavelike muscular contractions of the intestine (peristalsis) that ordinarily move food through the digestive tract stop.

Mechanical obstruction in infants

Infants under one year of age are most likely to have intestinal obstruction caused by meconium ileus, volvulus, and intussusception. Meconium ileus, which is the inability to pass the first fecal excretion after birth (meconium), is a disorder of newborns. It is an early clue that the infant has **cystic fibrosis**, but may also occur in very low birth weight (VLBW) infants. In meconium ileus, the material that is blocking the intestine is thick and stringy, rather than the collection of mucus and bile that is passed by normal infants. The abnormal meconium must be removed with an enema or through surgery.

Volvulus is the medical term for twisting of either the small or large bowel. The twisting may cut off the blood supply to the bowel, leading to tissue death (**gangrene**). This development is called a strangulating obstruction.

In intussusception, the bowel telescopes into itself like a radio antenna folding up. Intussusception is most common in children between the ages of three and nine months, although it also occurs in older children. Almost twice as many boys have intussusception as girls. It is difficult for doctors to predict which infants will have intestinal obstruction.

Mechanical obstruction in adults

Obstructions in adults are usually caused by tumors, **trauma**, volvulus, the presence of foreign bodies such as gallstones, or hernias, although they have also been reported in adults with cystic fibrosis. Volvulus occurs

most often in elderly adults and psychiatrically disturbed patients. Intussusception in adults is usually associated with tumors in the bowel, whether benign or malignant.

More recently, gastroenterologists have described a postsurgical complication known as early postoperative small bowel obstruction, or EPSBO. Although this condition was at one time confused with postoperative ileus, it is now known to be caused by mechanical obstructions resulting from **radiation therapy** for cancer or laparoscopic surgery. Most cases can be successfully treated within 10–14 days of surgery.

Causes and symptoms

Causes

Causes of intestinal obstructions can be subdivided into two primary groups: small bowel obstruction and large bowel obstruction. Causes of small bowel obstruction include:

- adhesions (usually from abdominal surgery, but sometimes present at birth)
- hernias (protrusion of intestines through the cavity that contains it)
- Crohn's disease (inflammatory disease of the intestines)
- neoplasm (abnormal growth of tissue mass)
- intussusception (layering [telescoping] of sections of intestines within other sections, children only)
- volvulus (abnormal twist in bowel)
- superior mesenteric artery syndrome (compression of part of duodenum by abdominal aorta and superior mesenteric artery)
- intestinal atresia (narrowing or absence of part of intestine)
- carcinoid (neuroendocrine tumor)
- foreign bodies (such as gall stones or swallowed objects)
- ischaemic stricture (abnormal narrowing of intestines usually at outlet from stomach)

Large bowel obstruction can be caused by the following:

- neoplasm
- hernias
- cancer
- inflammatory bowel disease (inflammation of the colon)
- diverticulitis (small pouches in digestive tract become inflamed or infected)
- colonic volvulus (twist in colon)
- fecal impaction (blocked, impacted feces in rectum)
- intestinal atresia
- endometriosis (uterine tissue found outside of uterus, in women only)

Almost all of the causes of intestinal obstructions occur in the small intestines rather than the large intestines.

Symptoms

One of the earliest signs of mechanical intestinal obstruction is abdominal **pain** or cramps that come and go in waves. Infants typically pull up their legs and cry in pain, then stop crying suddenly. They will then behave normally for as long as 15–30 minutes, only to start crying again when the next cramp begins. The cramping results from the inability of the muscular contractions of the bowel to push the digested food past the obstruction.

Vomiting is another symptom of intestinal obstruction. The speed of its onset is a clue to the location of the obstruction. Vomiting follows shortly after the pain if the obstruction is in the small intestine but it is delayed if found in the large intestine. The vomited material may be fecal in character. When the patient has a mechanical obstruction, the doctor will first hear active, high–pitched gurgling and splashing bowel sounds while listening with a stethoscope. Later these sounds decrease, and then stop. If the blockage is complete, the patient will not pass any gas or feces. If the blockage is only partial, the patient may have **diarrhea**. Initially there is little or no **fever**.

When the material in the bowel cannot move past the obstruction, the body reabsorbs large amounts of fluid and the abdomen becomes sore to the touch and swollen. The balance of certain important chemicals (electrolytes) in the blood is upset. Persistent vomiting can cause the patient to become dehydrated. Without treatment, the patient can develop **shock** and kidney failure.

Strangulation occurs when a loop of the intestine is cut off from its blood supply. Strangulation occurs in about 25% of cases of small bowel obstruction. It is a serious condition that can progress to gangrene within six hours.

Risks

The following pre–existing conditions can add to the risk of contracting intestinal obstructions:

- Crohn's disease
- abdominal or pelvic surgeries
- long–lasting constipation
- malrotation (congenital condition in which intestines do not develop normally)

WWW.BOOKBAZ.IR

If someone has advanced intestinal obstruction of one type or the other, certain symptoms will be apparent due to infection within the lining of the abdominal cavity (a condition known as **peritonitis**). These symptoms include:

- tenderness, pain, and swelling in abdominal area
- thirst, but low urine output
- fluid in abdomen
- vomiting and nausea
- fever and chills
- inability to pass gas or have a bowel movement

When advanced peritonitis occurs, more severe symptoms occur. They include:

- weak, rapid pulse
- either abnormally slow, shallow breathing or rapid breathing
- pale, clammy skin
- inability to pass gas or have a bowel movement
- dilated pupils in the eyes
- eyes that stare off into the distance

If such symptoms occur, the patient has most likely gone into shock, and immediate emergency care should be sought.

Diagnosis

Imaging studies

If the doctor suspects intestinal obstruction based on the **physical examination** and patient history, he or she will order x rays, a computed tomography scan (CT scan), or an **ultrasound** evaluation of the abdomen. In many cases the patient is given a **barium enema**. A suspension of barium sulfate, which is a white powder, is inserted through the rectum, and the intestinal area is photographed. Barium acts as a contrast material and allows the location of the obstruction to be visualized on film.

Laboratory tests

The first blood test of a patient with an intestinal obstruction usually gives normal results, but later tests indicate electrolyte imbalances. There is no way to determine if an obstruction is simple or strangulated except by performing surgery.

Treatment

Initial assessment

All patients with suspected intestinal obstruction are hospitalized. Treatment must be rapid, because strangulating obstructions can be fatal. The first step in treatment is inserting a **nasogastric tube** to suction out the contents of the stomach and intestines. The patient is then given intravenous fluids to prevent **dehydration** and correct electrolyte imbalances.

Nonsurgical approaches

Surgery can be avoided for some patients. In some cases of volvulus, guiding a rectal tube into the intestines will straighten the twisted bowels. In infants, a barium enema may reverse intussusception in 50–90% of the cases. An air enema is sometimes used instead of a barium enema. This treatment successfully relieves the obstruction in many infants. The children are usually hospitalized for observation for two to three days after these procedures. In patients with only partial obstruction, a barium enema may dissolve the blockage.

Surgical treatment

If these efforts fail, surgery is necessary. Strangulated obstructions require emergency surgery. The obstructed area is removed and part of the bowel is cut away. If the obstruction is caused by tumors, polyps, or scar tissue, they are removed. Hernias, if present, are repaired. **Antibiotics** are given to reduce the possibility of infection.

Alternatives

Alternative practitioners offer few suggestions for treatment. They focus on preventive strategies, particularly the use of high–fiber **diets** to keep the bowels healthy through regular elimination.

Prognosis

The prognosis for intestinal obstructions depends on age, previous illnesses (especially lung, heart, or kidney problems), and the specific cause of the obstruction within the intestines. Generally, healthy people have good prospects. However, when intestinal obstructions are associated with cancer, the prognosis is not as favorable.

Mortality

Untreated intestinal obstructions can be fatal. Delayed diagnosis of volvulus in infants has a mortality rate of 23–33% with prompt diagnosis and treatment the mortality rate is 3–9%. The bowel either strangulates or perforates, causing massive infection. Tissues within the intestines soon die, which leads to perforation of the intestines and infection. The patient eventually goes into shock. With prompt treatment,

KEY TERMS

Electrolytes—Salts and minerals that ionize in body fluids. Electrolytes control the body's fluid balance as well as performing other important functions.

Gangrene—The death of soft tissue in any part of the body when the blood supply is obstructed.

Ileus—Obstruction of the intestines caused by the absence of peristalsis.

Intussusception—The slipping or telescoping of one part of the intestine into the section next to it.

Meconium—A greenish fecal material that constitutes the first bowel movement of an infant.

Peristalsis—The waves of muscular contraction in the intestines that push the food along during the process of digestion.

Strangulated obstruction—An obstruction in which a loop of the intestine has its blood supply cut off.

Volvulus—A twisting of the intestine that causes an obstruction.

however, most patients recover successfully without complications.

Recurrence

As many as 80% of patients whose volvulus is treated without surgery have recurrences. Recurrences in infants with intussusception are most likely to happen during the first 36 hours after the blockage has been cleared. The mortality rate for unsuccessfully treated infants is 1–2%.

Prevention

Most cases of intestinal obstruction are not preventable. Surgery to remove tumors, polyps, or gallstones helps prevent recurrences. Other medical treatments and therapies may help to reduce the risk from many forms of intestinal obstructions.

Intestinal polyps

Definition

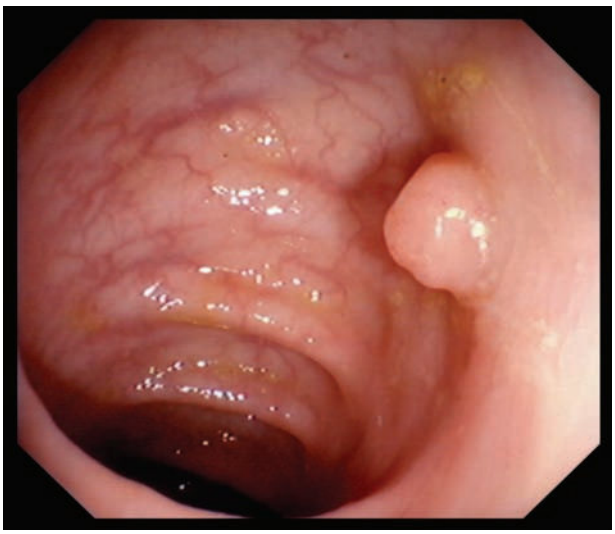
The word polyp refers to any overgrowth of tissue from the surface of mucous membranes. Intestinal polyps, sometimes also called colorectal polyps (or sometimes just colon polyps), grow out of the lining of the small and large bowels (intestines). Polyps come in a variety of shapes—round, droplet, and irregular being the most common. They also come in many sizes, from those smaller than a pea to others as large as a golf ball. Most are harmless but in a small percentage of cases they can become cancerous (colorectal cancer, or cancers of the colon and rectum) and dangerous to one's health and well–being, especially as one grows older.

Demographics

Intestinal polyps can occur in anyone, regardless of age or other characteristics. However, as one ages the likelihood of developing them increases. In fact, 50 years of age and older is the time when polyps are more likely to develop in humans. The risks from intestinal polyps can be reduced by eating a high–fiber, low–fat diet. A family history of intestinal polyps also increases one's risk of getting them.

The National Cancer Institute (NCI) predicted that about 102,900 new cases of **colon cancer** and

WWW.BOOKBAZ.IR



A benign polyp in a patients colon, viewed through an endoscope. *(Custom Medical Stock Photo, Inc.)*

approximately 39,670 new cases of **rectal cancer** would occur in the United States in 2010. In addition, NCI predicted that, in the same year, about 51,370 deaths would occur because of colon and rectal cancers (or, colorectal cancer).

Description

Polyps are one of many forms of tissue overproduction that can occur in the body. Cells in many body tissues sometimes keep growing beyond their usual limits. Medical scientists call this process *neoplasia*, which means simply "new growth." An individual overgrowth is called a neoplasm. In most cases these growths are limited, and the result is a benign swelling or mass of cells called a tumor. If the new growth occurs on the surface of the tissue instead of inside an organ it is often called a polyp. Cancer is another type of neoplasm marked by unlimited tissue growth. The essential feature that distinguishes cancer from nonmalignant neoplasms is that it does not stop growing.

Intestinal polyps are a common form of neoplasm. All intestinal polyps arise from the inner lining of the intestinal wall. This layer of mucosal tissue does the work of digestion. About 30% of the general population will develop intestinal polyps at some point in life, with the likelihood increasing with age. Most of these polyps are never noticed during a person's lifetime because they do not cause problems. They are often discovered accidentally at **autopsy**. The primary importance of intestinal polyps is that 1% of them become cancerous. Because the polyps that eventually turn malignant cannot be identified in advance, they are all suspect.

Location of intestinal polyps

The chances of a polyp's becoming cancerous depend to some extent on its location within the digestive tract.

COLON. Ninety–five percent of all intestinal polyps develop inside the large bowel. Several hereditary diseases produce large numbers of intestinal polyps. These disorders include:

- Familial polyposis of the colon.
- Gardner's syndrome.
- Lynch's syndrome.
- Turcot's syndrome.
- Peutz–Jeghers syndrome.
- Juvenile polyposis.

All of these disorders are inherited in an autosomal dominant pattern. This pattern means that the disorders are not sex–linked and that a child can inherit the disorder from either parent. In all of these hereditary disorders, the intestinal polyps appear during or after **puberty**. The first four diseases on the list have such a high rate of cancer of the large bowel (colon)—virtually 100% by the age of 40 years of age—that persons diagnosed with any of them should have the colon removed surgically in early adulthood.

STOMACH. The stomach's lining is host to polyps of a similar appearance, but there is no agreement as to their potential for becoming **stomach cancer**.

SMALL INTESTINE. Polyps in the small bowel do not seem to have malignant potential. Instead, they can produce obstruction in either of two ways. A large polyp can obstruct the bowel by its sheer size. Smaller polyps can be picked up by the rhythmic contractions (peristalsis) of the intestines and pull the part of the bowel to which they are attached into the adjoining section. The result is a telescoping of one section of bowel into another, called **intussusception**.

Causes and symptoms

Population studies of colon cancer suggest that age and diet play an important role in the disease, and, by implication, in the formation of colon polyps. Increased risk of colon cancer begins at the age of 40 years. Most people who have colon cancer are in their 50s or older. The most consistent interpretation of colon cancer data is that animal fats—though not vegetable fats—are the single most important dietary factor that raises the risk of colon polyps. Lack of fiber

KEY TERMS

Autosomal dominance—A pattern of heredity in which a trait is inherited without respect to sex and from either parent. The hereditary diseases associated with intestinal polyps are all autosomal dominant.

Colectomy—Surgical removal of the large bowel.

Intussusception—The slipping of one section of the intestine inside an adjoining section. Intussusception can be caused by small intestinal polyps.

Mucosal—Refers to tissues that produce mucus, such as the digestive, genital and urinary tracts.

Neoplasm—A new growth of abnormal tissue.

Peristalsis—The rhythmic contractions of muscular tubes like the intestines that carry the contents along the tube.

Sigmoid—The S–shaped curve of the large intestine where the colon joins the rectum.

in the diet may also contribute to polyp formation. Primarily, a person is at elevated risk for colon polyps if their diet consists of high fat, high percentage of red meat, and low fiber.

A family history of colon polyps or cancer also is a factor. The presence of inflammatory intestinal conditions, such as Crohn's disease and ulcerative **colitis**, also increases the risk of colon polyps. African Americans and Ashkenazi Jews of Eastern European descent are two groups of people with higher risk for colon cancer.

Lifestyle and the environment are also factors. Increased risk occurs when a person smokes tobacco products, drinks alcoholic beverages, and is obese (excessively overweight). In fact, smokers are approximately 20% more likely to develop colon polyps than are non–smokers. The more inactive one's lifestyle is, the more likely one will develop colon cancer. Exposure to carcinogenic substances (those known to cause cancer), such as asbestos, increases risks for colon cancer.

Three primary types of colon polyps occur: adenomatous polyps (most polyps are of this kind, but only a few become cancerous); hyperplastic polyps (second most frequent polyps, and they often occur in left colon and rectum); and inflammatory polyps (usually occur after ulcerative colitis or Crohn's disease). Most smaller sized polyps do not cause symptoms. However, larger ones eventually cause intestinal obstruction, which produces cramping abdominal **pain** with **nausea and vomiting**. As colon polyps evolve into cancers, they begin to produce symptoms that include rectal bleeding, blood in the stool, and altered bowel habits (including **constipation**, **diarrhea**, or narrowing of the stool).

Rectal bleeding may occur after a bowel movement. Such bleeding may be due to colon polyps, but may also be the result of **hemorrhoids** or minor tears in the anus. Blood in the stool, which may show up as red streaks within the stool or turn the stool black, can be an indication of colon polyps, but they may also be the result of eating red–colored foods (red streaks in the stool) or iron supplements and various anti–diarrhea medications (black stool). A change in bowel conditions can indicate the presence of colon polyps but can also be the result of other unrelated medical conditions.

Diagnosis

Routine screening for bowel cancer is recommended for everyone over the age of 50 years, and for those with a history of colorectal cancer over the age of 40 years. Medical professionals can test for some diseases that increase the risk for colorectal cancer, such as familial adenomatous polyposis (FAP) which increases one's risk for developing multiple colon polyps. Screening may be as simple as testing the stool for blood (such as through a **fecal occult blood test** [FOBT]) or as elaborate as **colonoscopy**. The FOBT is a noninvasive test that is often performed at the doctor' office or at home. Although it tests only for blood in the stool, the FOBT is a good beginning point for diagnosis.

A stool DNA test detects cancer cells that are present in the stool. Such cancer cells will have altered DNA, which makes this test advantageous for detecting pre–cancerous polyps and colon cancer. This test was approved by the U.S. Food and Drug Administration (FDA) in 2014.

Most polyps are in the lower segment of the colon, called the sigmoid colon. These polyps can be seen with a shorter scope (tube) called a flexible sigmoidoscope. Flexible **sigmoidoscopy** is a procedure that uses a narrow, lighted tube to examine the rectum and sigmoid (the last third of the colon). A **barium enema** is a diagnostic tool that evaluates the entire large intestine with a barium dye placed inside the

WWW.BOOKBAZ.IR

colon and an x-ray image. The colon is filled with barium sulfate (a white substance) that shows up as a shadow when imaged by an x-ray film. The colon can also be filled with barium sulfate and air, which is called a double contrast study.

Colonoscopy is a procedure in which the doctor threads an instrument called a colonoscope up through the entire large bowel. The colonoscope is a long, narrow tube attached to a video camera (for imaging inside the colon) and monitor (for viewing outside by the medical team). If one or more polyps are discovered during the examination, they can be removed. Computerized tomographic colonography (CTC) is a colonoscopy that is performed virtually (that is, without actually inserting an instrument inside the colon). It involves a CT scan of the colon. This three–dimensional look of the colon allows the medical professionals to make a detailed analysis of the colon. However, for this technique, any polyps discovered are not able to be removed.

Because polyps take about ten years to turn into cancers, routine examinations are recommended every three to five years.

Treatment

All polyps should be removed as preventive care. Most of them can be taken out through a colonoscope, in which the larger polyps are snared with a wire loop and the smaller ones are cauterized with an electrical current. Complications like obstruction and intussusception are surgical emergencies. The largest of the polyps can be removed with laparoscopic techniques, in which small incisions are cut into the abdominal wall so tiny instruments can be used to remove such polyps. Endoscopic mucosal resection (EMR) is a specialized procedure for removing large polyps with a colonoscope. The polyp is separated from other tissue with an injected liquid so the procedure can take place.

Chemotherapy, radiation, or a combination of the two is also used to treat colorectal cancer. In serious cases, parts of the colon may have to be removed. In more severe cases, a total proctocolectomy is performed, one in which all of the colon and rectum is removed.

Prognosis

Patients with intestinal polyps have an excellent outlook for the future once the polyps are removed. However, polyps left within the intestines can develop into cancer over time.

Prevention

Patients with hereditary disorders associated with polyps must undergo total colectomy early in adult life. All children of parents with these disorders should be screened early in adulthood, because half of them will have the same disease. For the bulk of the population, increased consumption of dietary fiber and decreased consumption of animal fat are the best preventives known at present. For the occasional intestinal polyp that arises in spite of good dietary habits, routine screening should prevent it from becoming cancerous.

Overall, the following are recommended to reduce the chances of developing colon polyps:

- Consume calcium and vitamin D, such as in no–fat or low–fat milk and other dairy products; some fish, and vitamin supplements.
- Consume fruits and vegetables, especially those high in antioxidants; those with deep green, dark yellow, dark orange colorings, such as squash, sweet potatoes, spinach, and broccoli; and those with lycopene such as tomatoes and red bell peppers and others with red colorings.
- Eat whole grains, such as those found in breads.
- Reduce unhealthy fats such as saturated fats and trans fats to less than 10% per day and total fats to less than 30% daily. When eating fats, select healthy ones such as unsaturated fats (monounsaturated and polyunsaturated fats).
- Limit alcohol consumption to one drink per day for women and two drinks per day for men.
- Stop using tobacco products such as cigarettes.
- Be as physically active as possible.
- Maintain a healthy mass to body index (BMI).

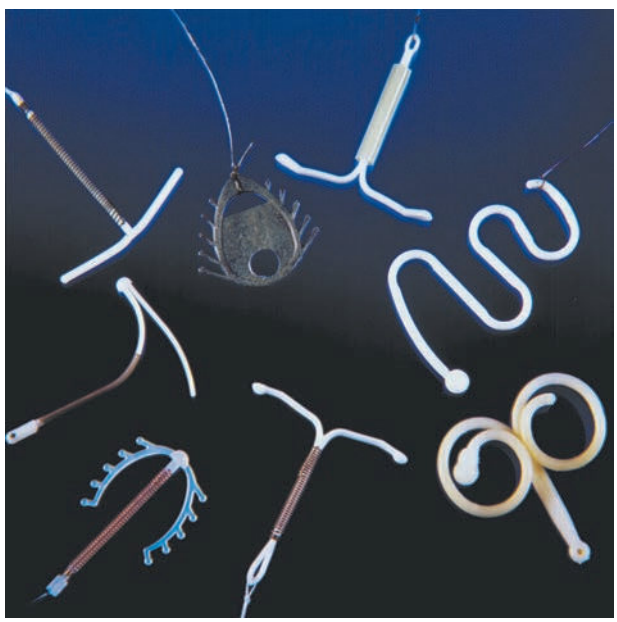
Intrauterine device

Definition

An intrauterine device (IUD) is a birth control (contraceptive) method made of plastic and/or copper that is inserted into the womb (uterus) by way of the vaginal canal. An IUD damages or kills sperm, preventing fertilization of the egg. Some types of IUDs thicken cervical mucus, which acts as a barrier to sperm entrance. IUDs may also make the lining of the uterus inhospitable to the implantation of a fertilized egg.



A variety of intrauterine contraceptive devices. The probability of a pregnancy for year of use is about 2–3%. IUDs made with copper coils should be replaced every 3 to 5 years. *(Photo Researchers, Inc.)*

Purpose

IUDs are used to prevent **pregnancy** and are considered to be 95–98% effective. It should be noted that IUDs offer no protection against the acquired immune deficiency syndrome (**AIDS**) virus or other sexually transmitted diseases (STDs).

Precautions

IUDs are placed in the uterus by physicians. Prior to placement the doctor will take a medical history, do a **physical examination**, and take a **Pap test**. Women who have had tubal pregnancies, an abnormal Pap smear, or abnormal vaginal bleeding are generally disqualified from using this form of **contraception**. Women who have STDs, an allergy to copper, severe **pain** with periods (menstruation), sex with multiple partners, or who are currently pregnant are not eligible for an IUD. There are no age restrictions.

Description

The IUD is a safe, effective, cost-effective, long-term, private, easily reversible form of birth control. One type exerts its affect due to the copper used to produce the device. The other type exerts its effect by slowly releasing the hormone progestin. Depending on the type of IUD, the device can be left in place for 3–10 years.

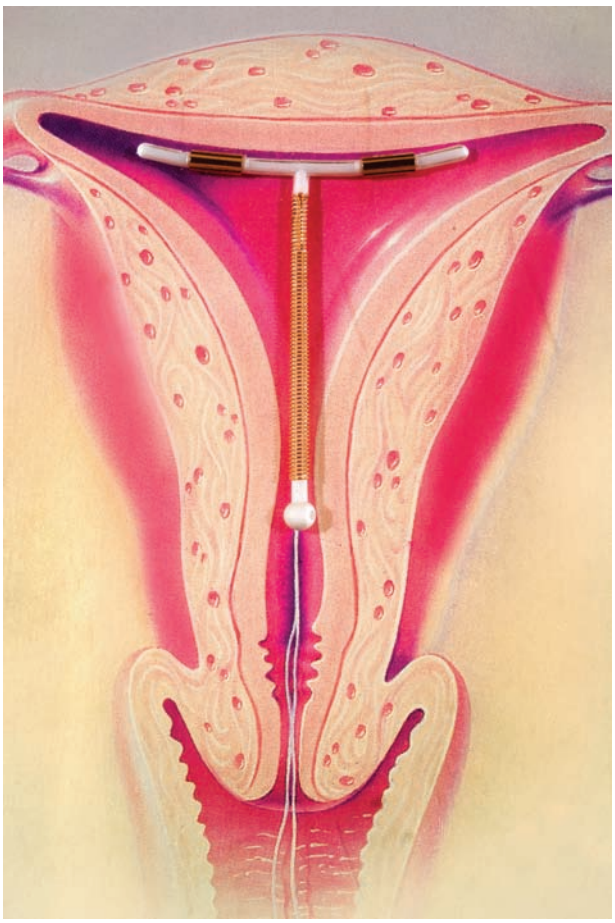
Preparation

After the physician approves the use of an IUD, the woman's genital area is washed thoroughly with soap and water in preparation of IUD insertion. The opening into the uterus (cervix) will also be cleaned with an antiseptic such as an iodine solution. Actual IUD insertion takes about five minutes, during which a local **anesthesia** is used to reduce any discomfort associated with the procedure. A plastic string connected to the IUD will hang out of the uterus into the vagina. The string is used to periodically check the position of the IUD.

Aftercare

The woman will be taught to watch for the signs and symptoms of potential complications and how to check the string, which should be done at least once a

WWW.BOOKBAZ.IR



An intrauterine device, inserted and used as a form of birth control. *(© Spencer Grant/Alamy.)*

week. To check the string, the woman should first wash her hands with soap and water. From a squatting position, or with one foot elevated (such as on a chair), she should gently insert her finger into the vagina until she nears the cervix. If she cannot feel the string, if the string feels longer than it should, or if she can feel part of the IUD, she should notify her physician immediately. Additional information that needs to be reported includes painful intercourse and unusual discharge from the vagina.

Risks

Serious risks are rare, but include heavy bleeding, pain, infection, cramps, **pelvic inflammatory disease**, perforation of the uterus, and **ectopic pregnancy**.

KEY TERMS

Antiseptic—A chemical that prevents the growth of germs.

Hormone—Chemicals that are produced in an organ or gland and then are carried by the blood to another part of the body where they produce a special effect for which they were designed.

Pap test—A procedure by which cells are collected from the cervix and vagina by inserting a swab into the vaginal canal. These cells are then examined under a microscope in order to detect signs of early cancer.

Intrauterine growth retardation

Definition

Intrauterine growth retardation (IUGR) occurs when the unborn baby (fetus) is at or below the 10th weight percentile for his or her gestational age (in weeks). In other words, the unborn baby is developing poorly (more slowly then normal) within the womb. After being born, these babies usually have low weights and are likely to continue having health problems later in life.

Description

There are standards or averages in weight for unborn babies according to their age in weeks. When the baby's weight is at or below the 10th percentile for his or her age, it is called intrauterine growth retardation, or fetal growth restriction. These babies are smaller than they should be for their age. How much a baby weighs at birth depends not only on how many

weeks old it is, but the rate at which it has grown. This growth process is complex and delicate. There are three phases associated with the development of the baby. During the first phase, cells multiply in the baby's organs. This occurs from the beginning of development through the early part of the fourth month. During the second phase, cells continue to multiply and the organs grow. In the third phase (after 32 weeks of development), growth occurs quickly and the baby may gain as much as 7 oz. (200 g) per week. If the delicate process of development and weight gain is disturbed or interrupted, the baby can have restricted growth.

IUGR is usually classified as symmetrical or asymmetrical. In symmetrical IUGR, the baby's head and body are proportionately small. In asymmetrical IUGR, the baby's brain is abnormally large when compared to the liver. In a normal infant, the brain weighs about three times as much as the liver. In asymmetrical IUGR, the brain can weigh five or six times as much as the liver.

Causes and symptoms

Doctors think that the two types of IUGR may be linked to the time during development that the problem occurs. Symmetrical IUGR may occur when the unborn baby experiences a problem during early development. Asymmetrical IUGR may occur when the unborn baby experiences a problem during later development. While not true for all asymmetrical cases, doctors think that sometimes the placenta may allow the brain to get more oxygen and **nutrition** while the liver gets less.

There are many IUGR risk factors involving the mother and the unborn baby. A mother is at risk for having a growth restricted infant if she:

- Has had a previous baby with IUGR
- Has poor weight gain and lack of nutrition (malnutrition) during pregnancy
- Is socially deprived
- Uses substances (like tobacco, narcotics, alcohol, and some prescription drugs, such as anticonvulsants) that can cause abnormal development or birth defects
- Has a vascular disease (like chronic hypertension [high blood pressure], preeclampsia [hypertension during pregnancy], or heart disease)
- Has chronic kidney disease
- Has sickle cell anemia
- Has a coagulation/antibody disorder called antiphospholipid antibody syndrome that causes blood clots
- Has a serious lung disease
- Has a low total blood volume during early pregnancy
- Is pregnant with more than one baby (multiple pregnancies)

A mother that is very small in size (weight) is more likely to have a fetus that is underweight when compared to normally sized unborn babies. Such a situation is not always caused by IUGR. About one out of three babies born smaller than normal have IUGR, while the other two are born smaller usually because the mother is smaller herself.

Additionally, an unborn baby may have IUGR if it has:

- Exposure to an infection, including German measles (rubella), cytomegalovirus, tuberculosis, syphilis, or toxoplasmosis
- A defect in the kidneys, abdominal wall, or in the cardiovascular system
- A chromosome defect, especially trisomy 18 (Edwards' syndrome), Down syndrome, or anencephaly (missing parts of the brain)
- A primary disorder of bone or cartilage
- A chronic lack of oxygen during development (hypoxia), such as from living at high altitudes
- Placenta or umbilical cord defects such as placenta previa (placenta too low in uterus) or placental abruption (placenta detaching from uterus)
- Developed outside of the uterus

Diagnosis

IUGR can be difficult to diagnose and in many cases doctors are not able to make an exact diagnosis until the baby is born. A mother who has had a growth–restricted baby is at risk of having another during a later **pregnancy**. Such mothers are monitored closely during pregnancy. The length in weeks of the pregnancy must be carefully determined so that the doctor will know if development and weight gain are appropriate.

Checking the mother's weight and abdomen measurements can help diagnose cases when other risk factors are not present. Measuring the girth of the abdomen is often used as a tool for diagnosing IUGR. During pregnancy, the healthcare provider will use a tape measure to record the height from the pubic bone to the top of the uterus (the uterine fundal height, in centimeters).

WWW.BOOKBAZ.IR

KEY TERMS

Preeclampsia—Hypertension (high blood pressure) during pregnancy.

As the pregnancy continues and the baby grows, the uterus stretches upward in the direction of the mother's head. Between 18 and 30 weeks of gestation, the uterine fundal height equals the weeks of gestation. For example, if the mother is 26 weeks pregnant, then the fundal height should be about 26 cm. If the uterine fundal height is more than 2–3 cm below normal, then IUGR is suspected. **Ultrasound** is used to evaluate the growth of the baby. Usually, IUGR is diagnosed after week 32 of pregnancy. This is during the phase of rapid growth when the baby should be gaining more weight. IUGR caused by genetic factors or infection may sometimes be detected earlier.

Treatment

Treatment is not available that improves fetal growth, but IUGR babies who are at or near term have the best outcome if delivered promptly. If IUGR is caused by a problem with the placenta and the baby is otherwise healthy, early diagnosis and treatment of the problem may reduce the chance of a serious outcome. Pregnant women suspected of carrying a fetus with IUGR will be monitored closely with several ultrasounds during the course of the pregnancy.

Measurements of movement, blood flow, growth, and fluid surrounding the fetus, will be carefully taken. Fetal monitoring is one test that indicates the health of a fetus. **Amniocentesis**, where a tiny amount of amniotic fluid is withdrawn from the uterus, is a way to test for chromosomal abnormalities.

A fetus that cannot tolerate the **stress** of natural labor may be delivered by **cesarean section** (c–section).

Prognosis

Babies who have IUGR are at an increased risk for intrauterine (inside the womb) death, stress during vaginal delivery, abnormally high red blood cell count, low blood sugar (**hypoglycemia**), low body temperature (**hypothermia**), lower resistance to infection, difficulty maintaining body temperature, and abnormal development of the nervous system. These risks increase with the severity of the growth restriction. The growth that occurs after birth cannot be predicted with certainty based on the size of the baby when it is born. Infants with asymmetrical IUGR are more likely to catch up in growth after birth than are infants who have prolonged symmetrical IUGR.

However, doctors cannot reliably predict an infant's future progress. Each case is unique. Some infants who have IUGR will develop normally, while others will have complications of the nervous system or intellectual problems like **learning disorders**. If IUGR is related to a disease or a genetic defect, the future of the infant is related to the severity and the nature of that disorder. Generally, most IUGR babies will attain a normal weight and height within two years of birth.

Prevention

The risk factors that can complicate pregnancies should be strictly controlled. Avoid alcohol, tobacco products, and drugs that are not part of the pregnancy. Make sure that regular prenatal care is obtained from medical professionals.

Movement of the unborn baby inside the mother is a reliable way to indicate its general health. A healthy baby moves and kicks often. Your caregiver may request a fetal kick count in between prenatal appointments to check on the number of kicks. A baby that has moved frequently in the past but has stopped kicking may be a sign of a problem. In such cases, call the pediatrician or other medical profession caring for the mother and baby.

The more nutrients that the mother takes in means the more nutrients for the unborn baby. Eat healthy foods and always go by the amount of calories recommended by the doctor. Plenty of rest is essential. At least eight hours of sleep each night should be taken by the mother, and naps during the day are also helpful.

Intravenous rehydration

Definition

Intravenous (IV) rehydration is a treatment for fluid loss in which a sterile water solution containing small amounts of salt or sugar is injected into the patient's bloodstream.

Purpose

Rehydration is usually performed to treat the symptoms associated with **dehydration**, or excessive loss of body water. **Fever**, **vomiting**, and **diarrhea** can cause a person to become dehydrated fairly quickly. Infants and children are especially vulnerable to dehydration. Patients can become dehydrated due to an illness, surgery, metabolic disorder, hot weather, or accident. Athletes who have overexerted themselves may also require rehydration with IV fluids. An IV for rehydration can be used for several hours to several days, and is generally used if a patient is unable to keep down oral fluids due to excessive vomiting.

Description

Intravenous rehydration is typically prescribed by a doctor and administered by a nurse, physician's assistant, or home healthcare aide. It may be performed in a hospital setting, an ambulatory care center, or a **home care** setting.

A basic IV rehydration solution consists of sterile water with small amounts of **sodium** chloride (NaCl; salt) and/or dextrose (sugar) added. It is supplied in bottles or thick plastic bags that can hang on a pole or rolling stand mounted next to a patient's bed. Additional electrolytes (potassium, **calcium**, bicarbonate, phosphate, magnesium, chloride), **vitamins**, or drugs can be added as needed either in a separate minibag or via an injection into the intravenous line.

Diagnosis

Signs and symptoms of dehydration include:

- extreme thirst
- sunken eyes
- reduced urine output; urine that is dark in color
- weakness and fatigue
- rapid weight loss
- dry, warm skin
- skin that is wrinkled or has little elasticity
- rapid pulse
- dry mouth
- "tearless" crying
- muscle cramps
- headache

In infants, dehydration may also be indicated by a sunken fontanelle (the soft spot on the head).

Preparation

If dehydration is confirmed, the doctor orders the IV solution and any additional nutrients or drugs that need to be added to it. The doctor also specifies the rate at which the IV will be infused. The intravenous solutions are prepared under the supervision of a pharmacist using sanitary techniques that prevent bacterial contamination. Just like a prescription, the IV is clearly labeled to show its contents and the amounts of any additives. A nurse will examine the patient's arm to find a suitable vein for insertion of the IV line. Once the vein is located, the skin around the area is cleaned and disinfected. The needle is inserted and is taped to the skin to prevent it from moving out of the vein.

Patients receiving IV therapy must be monitored to ensure that the IV solutions are providing the correct amounts of fluids and **minerals** needed. People with kidney and **heart disease** are at increased risk for **overhydration**, so they must be carefully monitored when receiving IV therapy.

Aftercare

Patients must be able to take (and keep down) fluids by mouth before an IV rehydration solution is discontinued. After the needle is removed, the

WWW.BOOKBAZ.IR

KEY TERMS

Dehydration—A condition that results from excessive loss of body water. The water may be lost through the digestive system, through sweating, or through the urinary tract.

Hypodermoclysis—A technique for restoring the body's fluid balance by injecting a solution of salt and water into the tissues beneath the skin rather than directly into a vein.

Intravenous—Into a vein; a needle is inserted into a vein in the back of the hand, inside the elbow, or some other location on the body.

insertion site should be inspected for any signs of bleeding or infection.

Risks

As with any invasive procedure, there is a small risk of infection or bruising at the injection site. It is possible that the IV solution may not provide all of the nutrients needed, leading to a deficiency or an imbalance. If the needle becomes dislodged, the solution may flow into tissues around the injection site rather than into the vein, resulting in swelling.

Morbidity and mortality rates

According to the United Nations Children's Fund (UNICEF), over two million children die of diarrhea-related dehydration each year. Eighty percent of these children were two years of age or younger. In the United States, an estimated 300 people (children and adults) die of dehydration annually.

Alternatives

For patients who are able to tolerate fluids by mouth, oral rehydration therapy (ORT) with oral rehydration salts (ORS) in solution is the preferred treatment alternative. Another technique in which fluid replacement is injected subcutaneously (under the skin into tissues) rather than into a vein is called hypodermoclysis. Hypodermoclysis is easier to administer than IV therapy, especially in the home setting. It may be used to treat mild to moderate dehydration in patients who are unable to take in adequate fluids by mouth and who prefer to be treated at home (geriatric or terminally ill patients).

Intravenous urography

Definition

Intravenous urography is a test that x rays the urinary system using intravenous dye for diagnostic purposes.

Of the many ways to obtain images of the urinary system, the intravenous injection of a contrast agent has been traditionally considered the best. The kidneys excrete the dye into the urine. X rays can then create pictures of every structure through which the urine passes.

The procedure has several variations and many names.

- Intravenous pyelography (IVP).
- Urography.
- Pyelography.
- Antegrade pyelography differentiates this procedure from "retrograde pyelography," which injects dye into the lower end of the system, therefore flowing backward or "retrograde." Retrograde pyelography is better able to define problems in the lower parts of the system and is the only way to get x rays if the kidneys are not working well.
- Nephrotomography is somewhat different in that the x rays are taken by a moving x ray source onto a film moving in the opposite direction. By accurately coordinating the movement, all but a single plane of tissue is blurred, and that plane is seen without overlying shadows.

Every method available gives good pictures of this system, and the question becomes one of choosing among many excellent alternatives. Each condition has special requirements, while each technique has distinctive benefits and drawbacks.

- Nuclear scans rely on the radiation given off by certain atoms. Chemicals containing such atoms are injected into the bloodstream. They reach the kidneys, where images are constructed by measuring the radiation emitted. The radiation is no more dangerous than standard x rays. The images require considerable training to interpret, but unique information is often available using this technology. Different chemicals can concentrate the radiation in different types of tissue. This technique may require several days for the chemical to concentrate at its destination. It also requires a special detector to create the image.
- Ultrasound is a quick, safe, simple, and inexpensive way to obtain views of internal organs. Although less detailed than other methods, it may be sufficient.
- Retrograde pyelography is better able to define problems in the lower parts of the system and is the only way to get x rays if the kidneys are not working well. Dye is usually injected through an instrument (cystoscope) passed into the bladder through the urethra.
- Computed tomography scans (CT or CAT scanning) uses the same kind of radiation used in x rays, but it collects information by computer in such a way that three dimensional images can be constructed, eliminating interference from nearby structures. CT scanning requires a special apparatus.
- Magnetic resonance imaging (MRI) uses magnetic fields and radio frequency signals, instead of ionizing radiation, to create computerized images. This form of energy is entirely safe as long as the patient has no metal in his or her body. The technique is far more versatile than CT scanning. MRI requires special apparatus and, because of the powerful magnets needed, even a special building all by itself. It is quite expensive.

Purpose

Most diseases of the kidneys, ureters, and bladder will yield information to this procedure, which actually has two phases. First, it requires a functioning kidney to filter the dye out of the blood into the urine. The time required for the dye to appear on x rays correlates accurately with kidney function. The second phase gives detailed anatomical images of the urinary tract. Within the first few minutes the dye "lights up" the kidneys, a phase called the nephrogram. Subsequent pictures follow the dye down the ureters and into the bladder. A final film taken after urinating reveals how well the bladder empties.

IVPs are most often done to assess structural abnormalities or obstruction to urine flow. If kidney function is at issue, more films are taken sooner to catch the earliest phase of the process.

- Stones, tumors and congenital malformations account for many of the findings.
- Kidney cysts and cancers can be seen.
- Displacement of a kidney or ureter suggests a space-occupying lesion like a cancer pushing it out of the way.
- Bad valves where the ureters enter the bladder will often show up.
- Bladder cancers and other abnormalities are often outlined by the dye in the bladder.
- An enlarged prostate gland will show up as incomplete bladder emptying and a bump at the bottom of the bladder.

Precautions

The only serious complication of an IVP is allergy to the iodine-containing dye that is used. Such an allergy is rare, but it can be dramatic and even lethal. Emergency measures taken immediately are usually effective.

Description

IVPs are usually done in the morning. In the x ray suite, the patient will undress and lie down. There are two methods of injecting the dye. An intravenous line can be established, through which the dye will be consistently fed through the body during the procedure. The other method is to give the dye all at once through

WWW.BOOKBAZ.IR

KEY TERMS

Contrast agent—Any substance that causes shadows on x rays, also known as contrast dye or medium.

Intravenous—Into a vein.

a needle that is immediately withdrawn. X rays are taken until the dye has reached the bladder, an interval of half an hour or less. The patient will be asked to empty the bladder before one last x ray.

Preparation

Emptying the bowel with **laxatives** or **enemas** prevents bowel shadows from obscuring the details of the urinary system. An empty stomach prevents the complications of **vomiting**, a rare effect of the contrast agent. Therefore, the night before the IVP the patient will be asked to evacuate the bowels and to drink sparingly.

Risks

Allergy to the contrast agent is the only risk. Anyone with a possible iodine allergy or a previous reaction to x-ray dye must be particularly careful to inform the x-ray personnel.

Intussusception

Definition

Intussusception is the enfolding of one segment of the intestine within another. It is characterized and initially presents with recurring attacks of cramping abdominal **pain** that gradually become more painful.

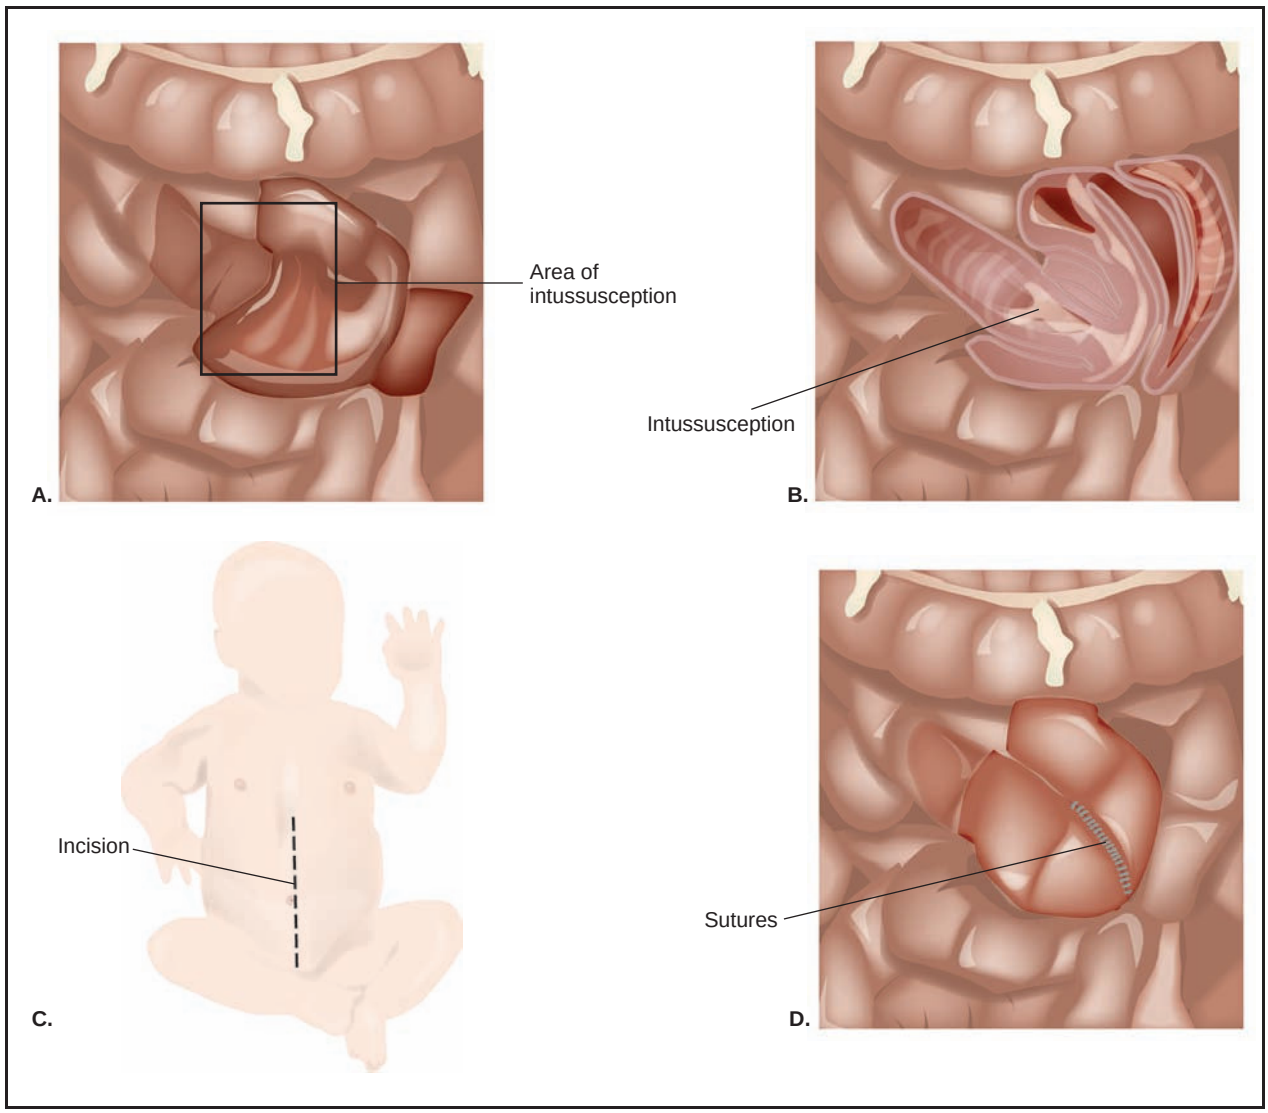
Description

Intussusception occurs when part of the bowel or intestine is wrapped around itself producing a mass-like object on the right side of the abdomen during palpation (a procedure used during a **physical examination**, when the examiner touches the abdomen with his/her hand, usually feeling for mass, pain, or discomfort). The number of new cases of intussuscetion is approximately 1.5–4 cases per 1,000 live births. The onset of abdominal pain is usually abrupt and severe. Just as fast as the onset of pain appears, it disappears and the child resumes activity normally. This process of sudden severe abdominal pain appearing out of the blue then disappearing is repeated with duration of painful attacks. The pain usually increases after approximately five hours of recurrent cycles of severe abdominal pain followed by relaxation. **Vomiting** and **diarrhea** occur in about 90% of cases within 6–12 hours after initial onset of symptoms.

Physical examination and palpation usually reveal a sausage shaped mass of enfolded bowel in the right upper mid portion of the abdomen. Within a few hours approximately 50% of cases have bloody, mucus filled bowel movements. At about this time the child is visibly very ill with **fever**, tenderness, and distended abdomen. Intussusception is the most frequent cause of intestinal obstruction during the first two years of life and commonly affects children 3–12 months of age. The disease is three times more common in males than in females. In about 85% of cases the cause is idiopathic (meaning unknown). The remaining 15% of cases can be caused by a variety of other diseases such as tumors of the lymph nodes (lymphoma), fat tumors (lipomas), foreign bodies/objects, or from infections that mobilize immune cells to the area causing an inflammatory reaction and intestinal blockage. Most cases of intussusception do not strangulate the affected bowel within the first 24 hours. If the disease is not treated after this time, the possibility of intestinal **gangrene**, **shock**, and death increases.

Causes and symptoms

The major symptom of intussusception is when a healthy child suddenly and without warning experiences severe abdominal pain that subsides and usually results in continuation of normal activities such as playing. The duration of the painful attacks increases as the hours go by. Usually, the child develops nausea, vomiting, and diarrhea soon afterwards in about 90% of all cases. The child becomes weak, exhausted, and develops a fever. The affected child may also expel bloody, mucus-like bowel movements. These blood filled bowel movements are usually due to impaired blood flow to the obstructed area. During palpation there may be a sausage-shaped mass located on the upper right mid portion of the abdomen. If the disease progresses and is



Intussusception of the bowel results in the bowel telescoping onto itself (A and B). To repair it, an incision is made in the baby's abdomen to expose the bowel (C). If the surgeon cannot manipulate the bowel into a normal shape manually, the area of intussusception will be removed and remaining bowel sutured together (D). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

undetected, the child may develop death of cells within the affected area. Additionally, there may be perforation or a hole in the intussusception bowel that can cause a life threatening infection in the peritoneum (a layer of tissue that protects the organs and intestines within the abdominal cavity). This infection of the peritoneum is called **peritonitis**. Some patients may exhibit altered states of consciousness or seizures.

Diagnosis

A presumed diagnosis can be made by history alone. If the clinician suspect's intussusception x-ray films should be performed, which may reveal a mass in the right upper mid abdominal region. Two classical clinical signs are mucus-blood filled stools and a "coiled string" appearance in the affected bowel as visualized during an x ray with a **barium enema**. Blood chemistry analysis is not specific for intussusception. Depending on vomiting and blood loss through the stools, blood chemistry may reflect signs of **dehydration** and anemia.

Treatment

Treating intussusception by reduction (alleviating the source of blockage) is an emergency procedure.

WWW.BOOKBAZ.IR

KEY TERMS

Barium—A chemical used in certain radiological studies to enhance visualization of anatomical structures.

Obstruction—A blockage that prevents movement.

The barium examination is not only the diagnostic tool of choice, but also frequently curative. Infusion by gravity from a catheter placed in the rectum will tend to relieve pressure buildup. If this does not relieve the area, then air can be pumped into the colon to clear blockage. If these procedures are unsuccessful then surgery is required. Approximately 25% of affected children require surgical intervention. Surgery in the affected bowel is advantageous since the actual cause can be removed, and the procedure decreases the possibility of recurrences. In general without surgical correction of the affected bowel, there is a 5–10% chance of recurrence. Recurrence usually appears within the first 24 to 48 hours after barium procedure.

Prognosis

The outcome of intussusception depends on the duration of symptoms before treatment initiation. Most infants will recover if treatment is initiated within the first 24 hours. Untreated intussusception is almost always fatal. Even with treatment, approximately 1–2% of affected children will die.

Prevention

Prevention of death can be accomplished with immediate medical care, within the first 24 hours. Once intussusception is suspected, emergency measures should be initiated. Untreated intussusception is almost always fatal. There is an increased chance for death if the disorder is not treated within 48 hours.

Ipecac

Definition

Ipecac syrup is a bitter tasting medicine that was formerly given to induce **vomiting** in cases of accidental **poisoning**.

Purpose

Nowadays, **activated charcoal** and gastric lavage (pumping the stomach) are more rapid and effective means of preventing serious illness and death from accidental poisoning.

In cases of acute poisoning, contact either the local poison control center, local hospital emergency room, or family doctor for instructions.

Ipecac syrup should never be used to induce vomiting if the poison is

- strong alkali (lye)
- strong acids (bleach)
- strychnine
- crude oil products like kerosene, fuel oil, gasoline, coal oil, paint thinner, or cleaning fluids

Ipecac should never be given to people who are drowsy, unconscious, or having difficulty swallowing.

Ipecac syrup is sometimes used to induce vomiting for weight control. This is dangerous and can cause

Ipecac plant (*Cephaelis ipecacuanha*). *(© Plantaphile.)*

heart problems and death. Additionally, violent retching and vomiting can cause tears in the esophagus resulting in vomiting blood, seizures, or even death.

Iron deficiency anemia

Definition

Anemia is a condition that results from insufficient numbers of healthy red blood cells, that. It can be caused by iron deficiency, folate deficiency, vitamin B_{12} deficiency, and other causes. The term iron deficiency anemia means anemia that is due to iron deficiency—that is, the insufficient dietary intake or absorption of iron in the body. Iron deficiency anemia is characterized by the production of smaller than normal red blood cells and less than the normal number of red cells in the blood. When examined under a microscope, the red blood cells also appear pale or light colored due to too little iron in the blood. For this reason, the anemia that occurs with iron deficiency is also called hypochronic microcytic anemia. Because fewer healthy red blood cells are produced (which causes less hemoglobin to be produced and, thus, less oxygen to be carried throughout the body), people with iron deficiency anemia often experience a lack of energy throughout their daily lives.

Demographics

Anyone has the potential for acquiring iron deficiency anemia. In the United States, approximately 20% of all women of child-bearing years, about 50% of pregnant women, and 2–3% of all men of similar ages have iron deficiency anemia. Women are generally at higher risk for iron deficiency anemia because they lose iron during menstruation.

Description

Iron deficiency anemia is the most common type of anemia throughout the world. In the United States, iron deficiency anemia occurs to a lesser extent than in developing countries because of the higher consumption of red meat and the practice of food fortification (addition of iron to foods by manufacturers). Anemia in the United States is caused by a variety of sources, including excessive losses of iron in menstrual fluids and excessive bleeding in the gastrointestinal tract. The condition can also be produced by **lead poisoning**, often in children ingesting lead-based paints while playing. In developing countries located in tropical climates, the most common cause of iron deficiency anemia is infestation with hookworm.

Risks

The following groups have more chance of getting iron deficiency anemia than other groups: women, infants and children, and people with certain medical conditions. Factors that can contribute to increased risk of iron deficiency anemia include: **pregnancy** (additional iron is needed for support of the fetus), heavy menstrual periods (which depletes iron in the body), low iron diet (such as vegetarian **diets** in which iron in allowed foods, such as vegetables, are not absorbed as well as iron in not-allowed foods, such as meat), and internal bleeding (such as from an ulcer or polyps). Donating blood and eating unhealthy foods on a regular basis are other ways to increase one' risk of iron deficiency anemia.

Causes and symptoms

Infancy is a period of increased risk for iron deficiency. The human infant is born with a built-in supply of iron, which can be tapped during periods of drinking low-iron milk or formula. Both human milk and cow milk contain rather low levels of iron (0.5–1.0 milligrams of iron per liter [mg iron/L]). However, the iron in human milk is about 50% absorbed by the infant, while the iron of cow milk is only 10% absorbed. During the first six months of life, growth of the infant is made possible by the milk in the diet and by the infant's built-in supply. Premature infants have a lower supply of iron and, for this reason, it is recommended that pre-term infants (beginning at 2 months of age) be given oral supplements of 7 mg iron/day, as ferrous sulfate. Iron deficiency can be provoked where infants are fed formulas that are based on unfortified cow milk. For example, unfortified cow milk is given free of charge to mothers in Chile. This practice has the

WWW.BOOKBAZ.IR

fortunate result of preventing general **malnutrition**, but the unfortunate result of the development of mild iron deficiency.

The normal rate of blood loss in the feces is 0.5–1.0 mL/day. These losses can increase with colorectal cancer. About 60% of colorectal cancers result in further blood losses, where the extent of blood loss is 2–10 mL/day. Cancer of the colon and rectum can provoke losses of blood, resulting in iron deficiency anemia. The fecal blood test is widely used to screen for the presence of cancer of the colon or rectum. In the absence of testing, colorectal cancer may be first detected because of the resulting iron deficiency anemia.

Infection with hookworm can provoke iron deficiency and iron deficiency anemia. The hookworm is a parasitic worm. It thrives in warm climates, including in the southern United States. The hookworm enters the body through the skin, as through bare feet. The hookworm then migrates to the small intestines where it attaches itself to the villi (small sausage-shaped structures in the intestines that are used for the absorption of all nutrients). The hookworm provokes damage to the villi, which results in blood loss. They also produce anti-coagulants, which promote continued bleeding. Each worm can provoke the loss of up to 0.25 mL of blood per day.

Bleeding and blood losses through gastrointestinal tract can be provoked by colorectal cancer and hookworms, but also by **hemorrhoids**, anal fissures, **irritable bowel syndrome**, aspirin-induced bleeding, blood clotting disorders, and **diverticulosis** (a condition caused by an abnormal opening from the intestine or bladder). Several genetic diseases exist that lead to bleeding disorders, and these include **hemophilia** A, hemophilia B, and von Willebrand's disease. Of these, only von Willebrand's disease leads to gastrointestinal bleeding.

The symptoms of iron deficiency anemia include weakness and **fatigue**. These symptoms result because of the lack of function of the red blood cells, and the reduced ability of the red blood cells to carry iron to exercising muscles. Iron deficiency can also affect other tissues, including the tongue and fingernails. Prolonged iron deficiency can result in changes of the tongue; it may become smooth, shiny, and reddened. This condition is called glossitis. The tongue may also become sore and inflamed. The fingernails may grow abnormally, acquiring a spoon-shaped appearance. They may also grow out brittle in texture and appearance.

The whites of the eyes may appear bluish in color. Other symptoms can include irritability, **headache**, cravings of food and other unusual substances while generally having a overall poor appetite, pale skin color, **shortness of breath**, irregular heartbeat, dizziness/lightheadedness, cold feeling of the extremities (hands and feet), and irritability. If iron deficiency anemia is mild, however, symptoms may not appear. Symptoms begin to show up as the condition worsens.

Decreased iron intake is a contributing factor in iron deficiency and iron deficiency anemia. The iron content of cabbage, for example, is about 1.6 mg/kg food, while that of spinach (33 mg/kg), lima beans (15 mg/kg), potatoes (14 mg/kg), tomatoes (3 mg/kg), apples (1.5 mg/kg), raisins (20 mg/kg), whole wheat bread (43 mg/kg), eggs (20 mg/kg), canned tuna (13 mg/kg), chicken (11 mg/kg), beef (28 mg/kg), corn oil (0.6 mg/kg), and peanut butter (6.0 mg/kg), are indicated. One can see that apples, tomatoes, and vegetable oil are relatively low in iron, while whole wheat bread, spinach, and beef are relatively high in iron. The assessment of whether a food is low or high in iron can also be made by comparing the amount of that food eaten per day with the recommended dietary allowance (RDA), which is part of the Dietary Reference Intakes (DRIs), for iron. The RDA for iron for the adult male (19 to 50 years of age) is 8 mg/day, while that for the adult woman (of the same age range) is 18 mg/day. For adult males and females (51 years and older) the RDA for iron is 8 mg/day. The RDA during pregnancy is 27 mg/day. The RDA for infants 7 to 12 months of age is 11 mg/day, for children 1 to 3 years of age it is 7 mg/day, for children 4 to 8 years it is 10 mg/day, for children 9 to 13 years it is 8 mg/day, and for children 14 to 18 years it is 11 mg/day for males and 15 mg/day for females. The RDA values are based on the assumption that the consumer eats a mixture of plant and animal foods.

Iron values alone may be deceptive, since the availability of iron in fruits, vegetables, and grains is very low, while that the availability from meat is much higher. The availability of iron in plants ranges from only 1–10%, while that in meat, fish, chicken, and liver is 20–30%. The term availability means the percent of dietary iron that is absorbed via the gastrointestinal tract to the bloodstream. Non-absorbed iron is lost in the feces.

Interactions between various foods can influence the absorption of dietary iron. Vitamin C can increase the absorption of dietary iron. Orange juice is a rich source of vitamin C. Thus, if a plant food, such as rice,

is consumed with orange juice, then the orange juice can enhance the absorption of the iron of the rice. Vitamin C is also added to infant formulas, and the increased use of formulas fortified with both iron and vitamin C has led to a marked decline in anemia in infants and young children in the United States. In contrast, if rice is consumed with tea, certain chemicals in the tea (tannins) can reduce the absorption of the iron. Phytic acid is a chemical that naturally occurs in legumes, cereals, and nuts. Phytic acid, which can account for 1–5% of the weight of these foods, is a potent inhibitor of iron absorption. The increased availability of the iron in meat products is partly due to the fact that heme-iron is absorbed to a greater extent than free iron salts, and to a greater extent than iron in the phytic acid/iron complex. Nearly all of the iron in plants is nonheme-iron. Much of the iron in meat is nonheme-iron as well. The nonheme-iron in meat, fish, chicken and liver may be about 20% available. The heme-iron of meat may be close to 30% available. The most available source of iron is human milk (50% availability).

Diagnosis

Iron deficiency anemia in infants is defined as a hemoglobin level below 109 mg/mL of whole blood, and a **hematocrit** (percentage of blood volume with respect to red blood cells) of under 33%. Anemia in adult males is defined as a hemoglobin under 130 mg/mL and a hematocrit of under 39%. Anemia in adult females is defined as hemoglobin under 120 mg/mL and a hematocrit of under 35%. Anemia in pregnant women is defined as hemoglobin of under 110 mg/mL and hematocrit of under 31%.

When an abnormally high presence of blood is found in the feces during a **fecal occult blood test**, the physician needs to examine the gastrointestinal tract to determine the cause of bleeding. Here, the diagnosis for iron deficiency anemia includes the examination using a sigmoidoscope. The sigmoidoscope is an instrument that consists of a flexible tube that permits examination of the colon to a distance of 24 in. (60 cm). A **barium enema**, with an x ray, may also be used to detect abnormalities that can cause bleeding.

The diagnosis of iron deficiency anemia should include a test for oral iron absorption, where evidence suggests that oral iron supplements fail in treating anemia. The oral iron absorption test is conducted by eating 64 mg iron (325 mg ferrous sulfate) in a single dose. Blood samples are then taken after 2 hours and 4 hours. The iron content of the blood serum is then measured. The concentration of iron should rise by an increment of about 22 micromolar, where iron absorption is normal. Lesser increases in concentration mean that iron absorption is abnormal, and that therapy should involve injections or infusions of iron.

Treatment

Oral iron supplements (pills) may contain various iron salts. These iron salts include ferrous sulfate, ferrous gluconate, or ferrous fumarate. These pills are most effective if they are taken on an empty stomach. Milk and **antacids** should not be taken with such pills. However, vitamin C, such as in orange juice, increases the absorption of iron. Injections and infusions of iron can be carried out with a preparation called iron dextran. In patients with poor iron absorption (by the gut), therapy with injection or infusion is preferable over oral supplements. Intravenous injections are often made into a vein or muscle. Treatment of iron deficiency anemia sometimes requires more than therapy with iron. Where hemorrhoids provoke iron deficiency, surgery may prove essential to prevent recurrent iron deficiency anemia. Where iron deficiency is provoked by bleeding due to **aspirin** treatment, aspirin should be discontinued. Where iron deficiency is provoked by hookworm infections, therapy for this parasite should be used, along with protection of the feet by wearing shoes whenever walking in hookworm-infested soil.

Prognosis

The prognosis for treating and curing iron deficiency anemia is excellent. The main problem is failure to take iron supplements. With adequate treatments, most cases of iron deficiency anemia goes away in a few weeks. In cases of pregnant women, the healthcare worker may recommend taking 100–200 mg iron/day. This dose is rather high, and can lead to nausea, **diarrhea**, or abdominal **pain** in 10–20% of women taking this dose. The reason for using this high dose is to affect a rapid cure for anemia, where the anemia is detected at a mid-point during the pregnancy. The above problems of side effects and noncompliance can be avoided by taking iron doses (100–200 mg) only once a week, where supplements are initiated some time prior to conception, or continuously throughout the fertile period of life. The problem of compliance is not an issue where infusions are used; however, a fraction of patients treated with iron infusions experience side effects, such as flushing, headache, nausea, **anaphylaxis**, or seizures. A number of studies have shown that iron deficiency anemia in infancy can result in reduced intelligence, where intelligence was measured in early

WWW.BOOKBAZ.IR

KEY TERMS

Hematocrit—The proportion of whole blood in the body, by volume, that is composed of red blood cells.

Hemoglobin—An iron-containing protein that resides within red blood cells. Hemoglobin accounts for about 95% of the protein in the red blood cell.

Protoporphyrin IX—A protein. The measurement of this protein is useful for the assessment of iron status. Hemoglobin consists of a complex of a protein plus heme. Heme consists of iron plus protoporphyrin IX. Normally, during the course of red blood cell formation, protoporphyrin IX acquires iron, to generate heme, and the heme becomes incorporated into hemoglobin. However, in iron deficiency, protophoryrin IX builds up.

Recommended Dietary Allowance (RDA)—The quantities of nutrients of the diet that are required to maintain human health. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences and may be revised every few years.

childhood. It is not certain if iron supplementation of children with reduced intelligence, due to iron-deficiency anemia in infancy, has any influence in allowing a "catch-up" in intellectual development.

If left untreated, iron deficiency anemia can lead to heart problems such as irregular or rapid heartbeat (as the heart tries to pump more blood that contains less oxygen) or **angina** (chest pains that occur when the heart does not receive sufficient oxygenated blood). It can also cause complications during pregnancy in women and delayed mental and physical growth spurts in children.

Prevention

In the healthy population, all of the mineral deficiencies can be prevented by the consumption of inorganic nutrients at levels defined by the RDA. Iron deficiency anemia in infants and young children can be prevented by the use of fortified foods. Liquid cow milk-based infant formulas are generally supplemented with iron (12 mg/L). The iron in liquid formulas is added as ferrous sulfate or ferrous gluconate. Commercial infant cereals are also fortified with iron, and here small particles of elemental iron are added. The levels used are about 0.5 gram iron/kg dry cereal. This amount of iron is about 10-fold greater than that of the iron naturally present in the cereal. Foods that are rich in iron include, poultry, red meat (such as liver), pork, seafood, egg yolks, whole-grain breads, raisins, legumes (such as beans and peas), dark green leafy vegetables (such as spinach), nuts and seeds and dried fruits (such as apricots and raisins). Many other foods are fortified with iron (such as breakfast foods).

Iron overload *see* **Hemochromatosis**

Iron tests

Definition

Iron tests are a group of blood tests that are done to evaluate the iron level in blood serum, the body's capacity to absorb iron, and the amount of iron actually stored in the body. Iron is an essential trace element; it is necessary for the formation of red blood cells and certain enzymes. At the other extreme, too much iron in the blood can be poisonous.

Purpose

There are four different types of tests that measure the body's iron levels and storage. They are called iron level tests, total iron-binding capacity (TIBC) tests,

ferritin tests, and transferrin tests. These tests are given for several reasons, including to:

- help in the differential diagnosis of different types of anemia
- assess the severity of anemia and monitor the treatment of patients with chronic anemia
- evaluate protein depletion and other forms of malnutrition
- check for certain liver disorders
- evaluate the possibility of chronic gastrointestinal bleeding; blood loss from the digestive tract is a common cause of iron-deficiency anemia
- help diagnose certain unusual disorders, including iron poisoning, thalassemia, hemosiderosis, and hemochromatosis

A serum iron test can be used without the others to evaluate cases of iron **poisoning**.

Description

Iron tests are performed on a sample of the patient's blood that has been withdrawn from a vein and placed in a vacuum tube. The amount of blood taken is between 6 mL and 10 mL (one-third of a fluid ounce). The procedure, called venipuncture, takes about five minutes.

Iron level test

The iron level test measures the amount of iron in the blood serum that is being carried by a protein (transferrin) in the blood plasma. Medications and substances that can cause increased iron levels include chloramphenicol, estrogen preparations, dietary iron supplements, alcoholic beverages, methyldopa, and birth control pills. Medications that can cause decreased iron levels include ACTH, colchicine, deferoxamine, methicillin, and testosterone.

Total iron-binding capacity (TIBC) test

The TIBC test measures the amount of iron that the blood would carry if the transferrin were fully saturated. Since transferrin is produced by the liver, the TIBC can be used to monitor liver function and **nutrition**. Medications that can cause increased TIBC levels include fluorides and birth control pills. Medications that can cause decreased TIBC levels include chloramphenicol and ACTH.

Transferrin test

The transferrin test is a direct measurement of transferrin—also called siderophilin—levels in the blood. Some laboratories prefer this measurement to the TIBC. The saturation level of the transferrin can be calculated by dividing the serum iron level by the TIBC.

Ferritin test

The ferritin test measures the level of a protein in the blood that stores iron for later use by the body. Medications that can cause increased ferritin levels include dietary iron supplements. In addition, some diseases that do not directly affect the body's iron storage can cause artificially high ferritin levels. These disorders include infections, late-stage cancers, lymphomas, and severe inflammations. People with a history of alcohol abuse often have high ferritin levels.

Precautions

Patients should not have their blood tested for iron within four days of a blood **transfusion** or tests and treatments that use radioactive materials. High **stress** levels or recent **sleep deprivation** are additional reasons for postponing iron tests.

Blood samples for iron tests should be taken early in the morning, because serum iron levels vary during the day. This precaution is especially important in evaluating the results of iron replacement therapy.

Preparation

Before patients are tested for iron, they should be checked for any of the following factors:

- use of prescription medications that affect iron levels, absorption, or storage
- blood transfusion or radioactive medications within the last four days
- recent extreme stress or sleep deprivation
- recent eating habits, especially consumption of large amounts of iron-rich foods

Patients scheduled for an iron level, TIBC, or transferrin test should fast for 12 hours before the blood is drawn, although they are allowed to drink water. Patients scheduled for a ferritin test do not need to fast but should not have any alcoholic beverages before the test.

Aftercare

Aftercare consists of applying pressure to the site of the blood draw and covering it with a bandage.

Risks

The primary risk is the possibility of a bruise or swelling in the area of the venipuncture. The patient

WWW.BOOKBAZ.IR

can apply moist warm compresses if there is any discomfort.

Results

Normal

IRON LEVEL TEST. Normal serum iron values are as follows:

- Adult males: 75–175 micrograms/dL
- Adult females: 65–165 micrograms/dL
- Children: 50–120 micrograms/dL
- Newborns: 100–250 micrograms/dL

TIBC TEST. Normal TIBC values are as follows:

- Adult males: 300–400 micrograms/dL
- Adult females: 300–450 micrograms/dL

TRANSFERRIN TEST. Normal transferrin values are as follows:

- Adult males: 200–400 mg/dL
- Adult females: 200–400 mg/dL
- Children: 203–360 mg/dL
- Newborns: 130–275 mg/dL

Normal transferrin saturation values are 30–40%.

FERRITIN TEST. Normal ferritin values are as follows:

- Adult males: 20–300 nanograms per mL
- Adult females: 20–120 ng/mL
- Children (one month): 200–600 ng/mL
- Children (two to five months): 50–200 ng/mL
- Children (six months to 15 years): 7–140 ng/mL
- Newborns: 25–200 ng/mL

Abnormal results

IRON LEVEL TEST. Serum iron level is increased in **thalassemia**, **hemochromatosis**, severe hepatitis, **liver disease**, **lead poisoning**, acute leukemia, and **kidney disease**. It is also increased by multiple blood transfusions and intramuscular iron injections. Iron levels above 350–500 micrograms/dL are considered toxic; levels over 1,000 micrograms/dL indicate severe iron poisoning.

Serum iron level is decreased in iron-deficiency anemia, chronic blood loss, chronic diseases (lupus, **rheumatoid arthritis**), late **pregnancy**, chronically heavy menstrual periods, and thyroid deficiency.

TIBC TEST. The TIBC is increased in iron-deficiency anemia, **polycythemia vera**, pregnancy, blood loss, severe hepatitis, and the use of birth control pills. It is decreased in people with **malnutrition**, severe **burns**, hemochromatosis, anemia caused by infections and chronic diseases, **cirrhosis** of the liver, or kidney disease.

TRANSFERRIN TEST. Transferrin is increased in iron-deficiency anemia, pregnancy, **hormone replacement therapy** (HRT), and the use of birth control pills. Transferrin is decreased in protein deficiency, liver damage, malnutrition, severe burns, kidney disease, chronic infections, and certain genetic disorders.

FERRITIN TEST. Ferritin is increased in liver disease, iron overload from hemochromatosis, certain types of anemia, acute leukemia, Hodgkin's lymphoma, **breast cancer**, thalassemia, infections, inflammatory diseases, and hemosiderosis. Ferritin levels may be normal or slightly above normal in patients with kidney disease.

Ferritin is decreased in chronic iron deficiency and severe protein depletion.

KEY TERMS

Anemia—A disorder marked by low hemoglobin levels in red blood cells, which leads to a deficiency of oxygen in the blood.

Ferritin—A protein found in the liver, spleen, and bone marrow that stores iron.

Hemochromatosis—A disorder of iron absorption characterized by bronze-colored skin. It can cause painful joints, diabetes, and liver damage if the iron concentration is not lowered.

Hemosiderosis—An overload of iron in the body resulting from repeated blood transfusions. Hemosiderosis occurs most often in patients with thalassemia.

Iron poisoning—A potentially fatal condition caused by swallowing large amounts of iron dietary supplements. Most cases occur in children who have taken adult-strength iron formulas. The symptoms of iron poisoning include vomiting, bloody diarrhea, convulsions, low blood pressure, and turning blue.

Plasma—The liquid part of blood.

Siderophilin—Another name for transferrin.

Thalassemia—A hereditary form of anemia that occurs most frequently in people of Mediterranean origin.

Transferrin—A protein in blood plasma that carries iron derived from food intake to the liver, spleen, and bone marrow.

Irritable bowel syndrome

Definition

Irritable bowel syndrome (IBS) is a common intestinal condition characterized by abdominal **pain** and cramps; changes in bowel movements (**diarrhea**, **constipation**, or both); gassiness; bloating; nausea; and other symptoms. There is no cure for IBS. Much about the condition remains unknown or poorly understood; however, dietary changes, drugs, and psychological treatment are often able to eliminate or substantially reduce its symptoms.

Demographics

It is unknown how many Americans have IBS. Surveys indicate a range of 10–20%, with perhaps as many as 30% of Americans experiencing IBS at some point in their lives. IBS normally makes its first appearance during young adulthood, and in half of all cases symptoms begin before age 35. Women with IBS outnumber men by two to one, for reasons that are not yet understood. IBS is responsible for more time lost from work and school than any medical problem other than the **common cold**. It accounts for more than half of all the patients seen by specialists in diseases of the digestive system (gastroenterologists). Yet only half—possibly as few as 15%–of people with IBS ever consult a doctor.

Description

IBS is the name people use today for a condition that was once called—among other things—colitis, mucous **colitis**, spastic colon, nervous colon, spastic bowel, and functional bowel disorder. Some of these names reflected the now outdated belief that IBS is a purely psychological disorder, a product of the patient's imagination. Although modern medicine recognizes that **stress** can trigger IBS attacks, medical specialists agree that IBS is a genuine physical disorder–or group of disorders–with specific identifiable characteristics.

Causes and symptoms

Symptoms

The symptoms of IBS tend to rise and fall in intensity rather than growing steadily worse over time. They always include abdominal pain, which may be relieved by defecation; diarrhea or constipation; or diarrhea alternating with constipation. Other symptoms—which vary from person to person—include cramps; gassiness; bloating; nausea; a powerful and uncontrollable urge to defecate (urgency); passage of a sticky fluid (mucus) during bowel movements; or the feeling after finishing a bowel movement that the bowels are still not completely empty. The accepted diagnostic criteria—known as the Rome

WWW.BOOKBAZ.IR

criteria—require at least three months of continuous or recurrent symptoms before IBS can be confirmed. According to the *American Family Physician,* an estimated 70% of IBS cases can be described as mild; 25% as moderate; and 5% as severe. In mild cases the symptoms are slight. As a general rule, they are not present all the time and do not interfere with work and other normal activities. Moderate IBS occasionally disrupts normal activities and may cause some psychological problems. People with severe IBS often find living a normal life impossible and experience crippling psychological problems as a result. For some the physical pain is constant and intense.

Causes

Researchers remain unsure about the cause or causes of IBS. It is called a functional disorder because it is thought to result from changes in the activity of the major part of the large intestine (the colon). After food is digested by the stomach and small intestine, the undigested material passes in liquid form into the colon, which absorbs water and salts. This process may take several days. In a healthy person the colon is quiet during most of that period except after meals, when its muscles contract in a series of wavelike movements called peristalsis. Peristalsis helps absorption by bringing the undigested material into contact with the colon wall. It also pushes undigested material that has been converted into solid or semisolid feces toward the rectum, where it remains until defecation. In IBS, however, the normal rhythm and intensity of peristalsis is disrupted. Sometimes there is too little peristalsis, which can slow the passage of undigested material through the colon and cause constipation. Sometimes there is too much, which has the opposite effect and causes diarrhea. A Johns Hopkins University study found that healthy volunteers experienced 6–8 contractions of the colon each day, compared with up to 25 contractions a day for volunteers having IBS with diarrhea, and an almost complete absence of contractions among constipated IBS volunteers. In addition to differences in the number of contractions, many of the IBS volunteers experienced powerful spasmodic contractions affecting a larger-than-normal area of the colon–"like having a Charlie horse in the gut," according to one of the investigators.

DIET. Some kinds of food and drink appear to play a key role in triggering IBS attacks. Food and drink that healthy people can ingest without any trouble may disrupt peristalsis in IBS patients, which probably explains why IBS attacks often occur shortly after meals. Chocolate, milk products, **caffeine** (in coffee, tea, colas, and other drinks), and large quantities of alcohol are some of the chief culprits. Other kinds of food have also been identified as problems, and the pattern of what can and cannot be tolerated is different for each person. Characteristically, IBS symptoms rarely occur at night and disrupt the patient's sleep.

STRESS. Stress is an important factor in IBS because of the close nervous system connections between the brain and the intestines. Although researchers do not yet understand all of the links between changes in the nervous system and IBS, they point out the similarities between mild digestive upsets and IBS. Just as healthy people can feel nauseated or have an upset stomach when under stress, people with IBS react the same way, but to a greater degree. Finally, IBS symptoms sometimes intensify during menstruation, which suggests that female reproductive hormones are another trigger.

Diagnosis

Diagnosing IBS is a fairly complex task because the disorder does not produce changes that can be identified during a **physical examination** or by laboratory tests. When IBS is suspected, the doctor (who can be either a family doctor or a specialist) needs to determine whether the patient's symptoms satisfy the Rome criteria. The doctor must rule out other conditions that resemble IBS, such as Crohn's disease and ulcerative colitis. These disorders are ruled out by questioning the patient about his or her physical and mental health (the medical history), performing a physical examination, and ordering laboratory tests. Normally the patient is asked to provide a stool sample that can be tested for blood and intestinal parasites. In some cases x rays or an internal examination of the colon using a flexible instrument inserted through the anus (a sigmoidoscope or colonoscope) is necessary. The doctor also may ask the patient to try a lactose-free diet for two or three weeks to see whether **lactose intolerance** is causing the symptoms.

Treatment

Dietary changes, sometimes supplemented by drugs or **psychotherapy**, are considered the key to successful treatment.

Mild symptoms

A low-fat, high-fiber diet is recommended. Problem-causing substances such as lactose, caffeine, beans,

cabbage, cucumbers, broccoli, fatty foods, alcohol, and medications should be identified and avoided. Bran or 15-25 g/day of an over-the-counter psyllium laxative (Metamucil or Fiberall) may also help both constipation and diarrhea. The patient can still have milk or milk products if lactose intolerance is not a problem. People with irregular bowel habits—particularly constipated patients—may be helped by establishing set times for meals and bathroom visits.

Moderate symptoms

In addition to the recommendations for mild symptoms, it is suggested that patients keep a diary of symptoms for two or three weeks, covering daily activities including meals, and emotional responses to events. The doctor can then review the diary with the patient to identify possible problem areas.

Although a high-fiber diet remains the standard treatment for constipated patients, such **laxatives** as lactulose (Chronulac) or sorbitol may be prescribed. Loperamide (Imodium) and cholestyramine (Questran) are suggested for diarrhea. Abdominal pain after meals can be reduced by taking **antispasmodic drugs** such as hyoscyamine (Anaspaz, Cystospaz, or Levsin) or dicyclomine (Bemote, Bentyl, or Di-Spaz) before eating.

Psychological counseling or behavioral therapy may be beneficial for some patients to reduce **anxiety** and to learn to cope with the pain and other symptoms of IBS. Relaxation therapy, hypnosis, **biofeedback**, and **cognitive-behavioral therapy** are examples of behavioral therapy.

Severe symptoms

When IBS produces constant pain that interferes with everyday life, **antidepressant drugs** can help by blocking pain transmission from the nervous system.

Alternatives

Alternative and mainstream approaches to IBS treatment overlap to a certain extent. Like mainstream doctors, alternative practitioners advise a high-fiber diet to reduce digestive system irritation. They also suggest avoiding alcohol, caffeine, and fatty, gassy, or spicy foods. Recommended stress management techniques include **yoga**, **meditation**, hypnosis, biofeedback, and **reflexology**. Reflexology is a technique of foot massage that is thought to relieve diarrhea, constipation, and other IBS symptoms.

KEY TERMS

Anus—The opening at the lower end of the rectum.

Crohn's disease—A disease characterized by inflammation of the intestines. Its early symptoms may resemble those of IBS.

Defecation—Passage of feces through the anus.

Feces—Undigested food and other waste that is eliminated through the anus. Feces are also called fecal matter or stools.

Lactose—A sugar found in milk and milk products. Some people are lactose intolerant, meaning they have trouble digesting lactose. Lactose intolerance can produce symptoms resembling those of IBS.

Peristalsis—The periodic waves of muscular contractions that move food through the intestines during the process of digestion.

Ulcerative colitis—A disease that inflames and causes breaks (ulcers) in the colon and rectum, which are parts of the large intestine.

Alternative medicine also emphasizes such herbal remedies as ginger (*Zingiber officinale*), buckthorn (*Rhamnus purshiana*), and enteric-coated peppermint oil. Enteric coating prevents digestion until the peppermint oil reaches the small intestine, thus avoiding irritation of the upper part of the digestive tract. Chamomile (*Matricaria recutita*), valerian (*Valeriana officinalis*), rosemary (*Rosemarinus officinalis*), lemon balm (*Melissa officinalis*), and other herbs are recommended for their antispasmodic properties. The list of alternative treatments for IBS is in fact quite long. It includes **aromatherapy**, homeopathy, **hydrotherapy**, juice therapy, **acupuncture**, **chiropractic**, **osteopathy**, **naturopathic medicine**, and Chinese traditional herbal medicine.

Prognosis

IBS is not a life-threatening condition. It does not cause intestinal bleeding or inflammation, nor does it cause other bowel diseases or cancer. Although IBS can last a lifetime, in up to 30% of cases the symptoms eventually disappear, and symptoms decrease significantly with treatment in about 60%. Even if the symptoms cannot be eliminated, with appropriate treatment they can usually be brought under control to the point where IBS becomes merely an occasional inconvenience. Treatment requires a long-term commitment, however; six months or more may be needed before the patient notices substantial improvement.

WWW.BOOKBAZ.IR

Prevention

Because the cause of IBS is not understood, there are no definitive ways to prevent it. However, some of the following may generally improve digestion:

- Drink sufficient water, about eight glasses per day
- Follow a high-fiber diet
- Avoid foods that cause discomfort. For some people, these include highly acidic or spicy foods, caffeinated beverages, and alcohol.
- Physical activity can help improve digestion
- Learn to avoid and cope with stress
- Eating many small meals a day is preferable to eating fewer very larfge meals
- Avoid medications that may cause constipation, or irritate the stomach

Howard Baker

Ischemia

Definition

Ischemia is an insufficient supply of blood to an organ, usually due to a blocked artery.

Description

Myocardial ischemia is an intermediate condition in **coronary artery disease** during which the **heart** tissue is slowly or suddenly starved of oxygen and other nutrients. Eventually, the affected heart tissue

This patient's foot is affected with ischemia. Ischemia occurs when there is an insufficient supply of blood to a specific organ or tissue. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

will die. When blood flow is completely blocked to the heart, ischemia can lead to a heart attack. Ischemia can be silent or symptomatic. According to the American Heart Association, up to four million Americans may have silent ischemia and be at high risk of having a heart attack with no warning.

Symptomatic ischemia is characterized by chest **pain** called **angina** pectoris. The American Heart Association estimates that nearly seven million Americans have angina pectoris, usually called angina. Angina occurs more frequently in women than in men, and in blacks and Hispanics more than in whites. It also occurs more frequently as people age—25% of women over the age of 85 and 27% of men who are 80–84 years old have angina.

People with angina are at risk of having a heart attack. Stable angina occurs during exertion, can be quickly relieved by resting or taking nitroglycerine, and lasts 3–20 minutes. Unstable angina, which increases the risk of a heart attack, occurs more frequently, lasts longer, is more severe, and may cause discomfort during rest or light exertion.

Ischemia can also occur in the arteries of the brain, where blockages can lead to a **stroke**. About 80–85% of all strokes are ischemic. Most blockages in the cerebral arteries are due to a blood clot, often in an artery narrowed by plaque. Sometimes, a blood clot in the heart or aorta travels to a cerebral artery. A transient ischemic attack (TIA) is a "mini-stroke" caused by a temporary deficiency of blood supply to the brain. It occurs suddenly, lasts a few minutes to a few hours, and is a strong warning sign of an impending stroke. Ischemia can also affect the intestines, legs, feet, and **kidneys**. Pain, malfunctions, and damage in those areas may result.

Causes and symptoms

Ischemia is almost always caused by blockage of an artery, usually due to atherosclerotic plaque. Myocardial ischemia is also caused by blood clots (which tend to form on plaque), artery spasms or contractions, or any of these factors combined. Silent ischemia is usually caused by emotional or mental **stress** or by exertion, but there are no symptoms. Angina is usually caused by increased oxygen demand when the heart is working harder than usual—for example, during **exercise**, or during mental or physical stress. According to researchers at Harvard University, physical stress is harder on the heart than mental stress. A TIA is caused by a blood clot briefly blocking a cerebral artery.

Risk factors

The risk factors for myocardial ischemia are the same as those for coronary artery disease. For TIA, coronary artery disease is also a risk factor. Risk factors include:

- Heredity. People whose parents have coronary artery disease are more likely to develop it. African Americans are also at higher risk.
- Sex. Men are more likely to have heart attacks than women, and to have them at a younger age.
- Age. Men who are 45 years of age and older and women who are 55 years of age and older are considered to be at risk.
- Smoking. Smoking increases both the chance of developing coronary artery disease and the chance of dying from it. Secondhand smoke may also increase risk.
- High cholesterol. Risk of developing coronary artery disease increases as blood cholesterol levels increase. When combined with other factors, the risk is even greater.
- High blood pressure. High blood pressure makes the heart work harder, and, with time, weakens it. When combined with obesity, smoking, high cholesterol, or diabetes, the risk of heart attack or stroke increases several times.
- Lack of physical activity. Lack of exercise increases the risk of coronary artery disease.
- Diabetes mellitus. The risk of developing coronary artery disease is seriously increased for diabetics.
- Obesity. Excess weight increases the strain on the heart and increases the risk of developing coronary artery disease, even if no other risk factors are present. Obesity increases blood pressure and blood cholesterol, and can lead to diabetes.
- Stress and anger. Some scientists believe that stress and anger can contribute to the development of coronary artery disease. Stress increases the heart rate and blood pressure and can injure the lining of the arteries. Angina attacks often occur after anger, as do many heart attacks and strokes.

Angina symptoms include:

- a tight, squeezing, heavy, burning, or choking pain that is usually beneath the breastbone—the pain may spread to the throat, jaw, or one arm
- a feeling of heaviness or tightness that is not painful
- a feeling similar to gas or indigestion
- attacks brought on by exertion and relieved by rest

WWW.BOOKBAZ.IR

If the pain or discomfort continues or intensifies, immediate medical help should be sought, ideally within 30 minutes.

TIA symptoms include:

- sudden weakness, tingling, or numbness, usually in one arm or leg or both the arm and leg on the same side of the body, as well as sometimes in the face
- sudden loss of coordination
- loss of vision or double vision
- difficulty speaking
- vertigo and loss of balance

Diagnosis

Diagnostic tests for myocardial ischemia include resting, exercise, or ambulatory electrocardiograms; scintigraphic studies (radioactive heart scans); **echocardiography**; coronary **angiography**; and, rarely, **positron emission tomography** (PET). Diagnostic tests for TIA include physician review of symptoms, **computed tomography scans** (**CT scans**), carotid artery ultrasound (**Doppler ultrasonography**), and **magnetic resonance imaging**. Angiography is the best test for ischemia of any organ.

An electrocardiogram (ECG) shows the heart's activity and may reveal a lack of oxygen. Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. Impulses of the heart's activity are recorded on paper. The test takes about 10 minutes and is performed in a physician's office. About 25% of patients with angina have normal electrocardiograms. Another type of electrocardiogram, the exercise **stress test**, measures response to exertion when the patient is exercising on a treadmill or a stationary bike. It is performed in a physician's office or an exercise laboratory and takes 15 to 30 minutes. This test is more accurate than a resting ECG in diagnosing ischemia. Sometimes an ambulatory ECG is ordered. For this test, the patient wears a portable ECG machine called a Holter monitor for 12, 24, or 48 hours.

Myocardial perfusion scintigraphy and radionuclide angiography are nuclear studies involving the injection of a radioactive material (e.g., thallium), which is absorbed by healthy tissue. A gamma scintillation camera displays and records a series of images of the radioactive material's movement through the heart. Both tests are usually performed in a hospital's nuclear medicine department and take about 30 minutes to an hour. A perfusion scan is sometimes performed at the end of a stress test.

An echocardiogram uses sound waves to create an image of the heart's chambers and valves. The technician applies gel to a handheld transducer, then presses it against the patient's chest. The heart's sound waves are converted into an image on a monitor. Performed in a cardiology outpatient diagnostic laboratory, the test takes 30 minutes to an hour. It can reveal abnormalities in the heart wall that indicate ischemia, but it does not evaluate the coronary arteries directly.

Coronary angiography is the most accurate diagnostic technique, but it is also the most invasive. It shows the heart's chambers, great vessels, and coronary arteries by using a contrast solution and x-ray technology. A moving picture is recorded of the blood flow through the coronary arteries. The patient is awake, but sedated, and connected to ECG electrodes and an intravenous line. A local anesthetic is injected. The cardiologist then inserts a catheter into a blood vessel and guides it into the heart. Coronary angiography is performed in a **cardiac catheterization** laboratory and takes from half an hour to two hours.

Positron emission tomography (PET) is a noninvasive nuclear test used to evaluate the heart tissue. A PET scanner traces high-energy gamma rays released from radioactive particles to provide three-dimensional images of the heart tissue. Performed at a hospital, it usually takes from one hour to one hour and 45 minutes. PET is very expensive and not widely available.

Computed tomography scans (CT scans) and magnetic resonance imaging (MRI) are computerized scanning methods. CT scanning uses a thin x-ray beam to show three-dimensional views of soft tissues. It is performed at a hospital or clinic and takes less than a minute. MRI uses a magnetic field to produce clear, cross-sectional images of soft tissues. The patient lies on a table that slides into a tunnel-like scanner. It is usually performed at a hospital and takes about 30 minutes.

Treatment

Angina is treated with drug therapy and surgery. Drugs such as nitrates, beta-blockers, and **calcium** channel blockers relieve chest pain, but they cannot clear blocked arteries. Aspirin helps prevent blood clots. Surgical procedures include percutaneous transluminal coronary **angioplasty** and **coronary artery bypass graft surgery**.

Nitroglycerin is the classic treatment for angina. It quickly relieves pain and discomfort by opening the coronary arteries and allowing more blood to flow to the heart. Beta blockers reduce the amount of oxygen

required by the heart during stress. Calcium channel blockers help keep the arteries open and reduce **blood pressure**. Aspirin helps prevent blood clots from forming on plaques.

Percutaneous transluminal coronary angioplasty and coronary artery bypass graft surgery are invasive procedures that improve blood flow in the coronary arteries. Percutaneous transluminal coronary angioplasty is a non-surgical procedure in which a catheter tipped with a balloon is threaded from a blood vessel in the thigh into the blocked artery. The balloon is inflated, compressing the plaque to enlarge the blood vessel and open the blocked artery. The balloon is deflated and the catheter is removed. The procedure is performed by a cardiologist in a hospital and generally requires a two-day stay. Sometimes a metal stent is placed in the artery to prevent closing of the artery.

In coronary artery bypass graft, called bypass surgery, a detour is built around the coronary artery blockage with a healthy leg vein or chest wall artery. The healthy vein or artery then supplies oxygen-rich blood to the heart. Bypass surgery is major surgery appropriate for patients with blockages in two or three major coronary arteries or severely narrowed left main coronary arteries, as well as those who have not responded to other treatments. It is performed in a hospital under **general anesthesia** using a heart-lung machine to support the patient while the healthy vein or artery is attached to the coronary artery.

There are several experimental surgical procedures: atherectomy, where the surgeon shaves off and removes strips of plaque from the blocked artery; laser angioplasty, where a catheter with a laser tip is inserted to burn or break down the plaque; and insertion of a metal coil, called a stent, that can be implanted permanently to keep a blocked artery open. This **stenting** procedure is becoming more common. Another experimental procedure uses a laser to drill channels in the heart muscle to increase blood supply.

TIAs are treated by drugs that control high blood pressure and reduce the likelihood of blood clots and surgery. Aspirin is commonly used, and anticoagulants are sometimes used to prevent blood clots. In some cases, carotid endarterectomy surgery is performed to help prevent further TIAs. The procedure involves removing arterial plaque from inside **blood vessels**.

The use of chelation therapy, a long-term injection by a physician of a cocktail of synthetic amino acid, ethylenediaminetetracetric acid, and **anticoagulant drugs** and nutrients, is controversial.

Alternatives

Ischemia can be life-threatening. Although there are alternative treatments for angina, traditional medical care may be necessary. Prevention of the cause of ischemia, primarily **atherosclerosis**, is primary. This becomes even more important for people with a family history of heart disease. Dietary modifications, especially the reduction or elimination of saturated fats (primarily found in meat), are essential. Increased fiber (found in fresh fruits and vegetables, grains, and beans) can help the body eliminate excessive **cholesterol** through the stools. Exercise, particularly aerobic exercise, is essential for circulation health. Not **smoking** will prevent damage from smoke and the harmful substances it contains.

Abana, a mixture of herbs and **minerals** used in Ayurvedic medicine, can reduce the frequency and severity of angina attacks. Western herbal medicine recommends hawthorn (*Crataegus laevigata* or *C. oxyacantha*) to relieve long-term angina, since it strengthens the contractility of the heart muscles. **Nutritional supplements** and botanical medicines that act as antioxidants—for example, **vitamins** C and E, selenium, gingko (*Gingko biloba*), bilberry (*Vaccinium myrtillus*), and hawthorn—can help prevent initial arterial injury that can lead to the formation of plaque deposits. Cactus (*Cactus grandiflorus*) is a homeopathic remedy used for pain relief during an attack. Mind/body **relaxation** techniques such as **yoga** and biofeedback can help control strong emotions and stress.

Prognosis

In many cases, ischemia can be successfully treated, but the underlying disease process of atherosclerosis is usually not cured. New diagnostic techniques enable doctors to identify ischemia earlier. New technologies and surgical procedures can prevent angina from leading to a heart attack or TIA from resulting in a stroke. The outcome for patients with silent ischemia has not been well established.

Prevention

A healthy lifestyle, including eating right, getting regular exercise, maintaining a healthy weight, not smoking, drinking in moderation, not using illegal drugs, controlling **hypertension**, and managing stress, are practices that can reduce the risk of ischemia progressing to a heart attack or stroke.

A healthy diet includes a variety of foods that are low in fat, especially saturated fat; low in cholesterol; and high in fiber. Plenty of fruits and vegetables

WWW.BOOKBAZ.IR

KEY TERMS

Atherosclerosis—A process in which the walls of the arteries thicken due to the accumulation of plaque in the blood vessels. Atherosclerosis is the cause of most coronary artery disease.

Coronary artery disease—A narrowing or blockage, due to atherosclerosis, of the arteries that provide oxygen and nutrients to the heart. When blood flow is cutoff, the result is a heart attack.

Plaque—A deposit of fatty and other substances that accumulate in the lining of the artery wall.

Stroke—A sudden decrease or loss of consciousness caused by rupture or blockage of a blood vessel by a blood clot or hemorrhage in the brain. Ischemic strokes are caused by blood clots in a cerebral artery.

should be eaten and sodium should be limited. Fat should comprise no more than 30% of total daily calories. Cholesterol should be limited to about 300 mg and sodium to about 2,400 mg per day.

Moderate aerobic exercise lasting about 30 minutes four or more times per week is recommended for maximum heart health, according to the Centers for Disease Control and Prevention and the American College of Sports Medicine. Three 10-minute exercise periods are also beneficial. If any risk factors are present, a physician's clearance should be obtained before starting exercise.

Maintaining a desirable body weight is also important. People who are 20% or more over their ideal body weight have an increased risk of developing coronary artery disease or stroke.

Smoking has many adverse effects on the heart and arteries and should be avoided. Heart damage caused by smoking can be improved by quitting. Several studies have shown that ex-smokers face the same risk of heart disease as non-smokers within 5–10 years of quitting.

Excessive drinking can increase risk factors for heart disease. Modest consumption of alcohol, however, can actually protect against coronary artery disease. The American Heart Association defines moderate consumption as one ounce of alcohol per day—roughly one cocktail, one 8-oz. glass of wine, or two 12-oz. glasses of beer.

Commonly used illegal drugs can seriously harm the heart and should never be used. Even stimulants like ephedra and decongestants like pseudoephedrine can be harmful to patients with hypertension or heart disease.

Treatment should be sought for hypertension. High blood pressure can be completely controlled through lifestyle changes and medication. Stress, which can increase the risk of a heart attack or stroke, should also be managed. While it cannot always be avoided, it can be controlled.

Isolation

Definition

Isolation refers to the precautions that are taken in the hospital to prevent the spread of an infectious agent from an infected or colonized patient to susceptible persons.

Purpose

Isolation practices are designed to minimize the transmission of infection in the hospital, using current understanding of the way infections can transmit. Isolation should be done in a user friendly, well-accepted, inexpensive way that interferes as little as possible with patient care, minimizes patient discomfort, and avoids unnecessary use.

Precautions

The type of precautions used should be viewed as a flexible scale that may range from the least to the most demanding methods of prevention. These methods should always take into account that differences exist in the way that diseases are spread. Recognition

and understanding of these differences will avoid use of insufficient or unnecessary interventions.

Description

Isolation practices can include placement in a private room or with a select roommate, the use of protective barriers such as masks, gowns and gloves, a special emphasis on handwashing (which is always very important), and special handling of contaminated articles. Because of the differences among infectious diseases, more than one of these precautions may be necessary to prevent spread of some diseases but may not be necessary for others.

The Centers for Disease Control and Prevention (CDC) and the Hospital **Infection Control** Practice Advisory Committee (HICPAC) have led the way in defining the guidelines for hospital-based infection precautions. The most current system recommended for use in hospitals consists of two levels of precautions. The first level is Standard Precautions that apply to all patients at all times because signs and symptoms of infection are not always obvious and may unknowingly pose a risk for a susceptible person. The second level is known as Transmission-Based Precautions, which are intended for individuals who have a known or suspected infection with certain organisms.

Frequently, patients are admitted to the hospital without a definite diagnosis, but with clues to suggest an infection. These patients should be isolated with the appropriate precautions until a definite diagnosis is made.

Standard Precautions

Standard Precautions define all the steps that should be taken to prevent spread of infection from person to person when there is an anticipated contact with:

- Blood
- Body fluids
- Secretions, such as phlegm
- Excretions, such as urine and feces (not including sweat) whether or not they contain visible blood
- Nonintact skin, such as an open wound
- Mucous membranes, such as the mouth cavity

Standard Precautions includes the use of one or combinations of the following practices. The level of use will always depend on the anticipated contact with the patient:

- Handwashing, the most important infection control method
- Use of latex or other protective gloves
- Masks, eye protection and/or face shield
- Gowns
- Proper handling of soiled patient care equipment
- Proper environmental cleaning
- Minimal handling of soiled linen
- Proper disposal of needles and other sharp equipment such as scalpels
- Placement in a private room for patients who cannot maintain appropriate cleanliness or contain body fluids

Transmission Based Precautions

Transmission Based Precautions may be needed in addition to Standard Precautions for selected patients who are known or suspected to harbor certain infections. These precautions are divided into three categories that reflect the differences in the way infections are transmitted. Some diseases may require more than one isolation category.

AIRBORNE PRECAUTIONS. Airborne Precautions prevent diseases that are transmitted by minute particles called droplet nuclei or contaminated dust particles. These particles, because of their size, can remain suspended in the air for long periods of time; even after the infected person has left the room. Some examples of diseases requiring these precautions are **tuberculosis**, **measles**, and **chickenpox**.

A patient needing Airborne Precautions should be assigned to a private room with special ventilation requirements. The door to this room must be closed at all possible times. If a patient must move from the isolation room to another area of the hospital, the patient should be wearing a mask during the transport. Anyone entering the isolation room to provide care to the patient must wear a special mask called a respirator.

DROPLET PRECAUTIONS. Droplet Precautions prevent the spread of organisms that travel on particles much larger than the droplet nuclei. These particles do not spend much time suspended in the air, and usually do not travel beyond a several foot range from the patient. These particles are produced when a patient coughs, talks, or sneezes. Examples of disease requiring droplet precautions are meningococcal **meningitis** (a serious bacterial infection of the lining of the brain), **influenza**, **mumps**, and German measles (**rubella**).

Patients who require Droplet Precautions should be placed in a private room or with a roommate who is

WWW.BOOKBAZ.IR

KEY TERMS

Colonized—This occurs when a microorganism is found on or in a person without causing a disease.

Disinfected—Decreased the number of microorganisms on or in an object.

Latex—A rubber material that gloves and condoms are made from.

Phlegm—Another word for sputum; material coughed up from a person's airways.

Stethoscope—A medical instrument for listening to a patient's heart and lungs.

infected with the same organism. The door to the room may remain open. Healthcare workers will need to wear masks within 3 ft (1 m) of the patient. Patients moving about the hospital away from the isolation room should wear a mask.

CONTACT PRECAUTIONS. Contact Precautions prevent spread of organisms from an infected patient through direct (touching the patient) or indirect (touching surfaces or objects that have been in contact with the patient) contact. Examples of patients who might be placed in Contact Precautions are those infected with:

- Antibiotic-resistant bacteria
- Hepatitis A
- Scabies
- Impetigo
- Lice

This type of precaution requires the patient to be placed in a private room or with a roommate who has the same infection. Healthcare workers should wear gloves when entering the room. They should change their gloves if they touch material that contains large volumes of organisms such as soiled dressings. Prior to leaving the room, healthcare workers should remove the gloves and wash their hands with medicated soap. In addition, they may need to wear protective gowns if there is a chance of contact with potentially infective materials such as **diarrhea** or wound drainage that cannot be contained or if there is likely to be extensive contact with the patient or environment.

Patient care items, such as a stethoscope, that are used for a patient in Contact Precautions should not be shared with other patients unless they are properly cleaned and disinfected before reuse. Patients should leave the isolation room infrequently.

Itching

Definition

Itching is an intense, distracting irritation or tickling sensation that may be felt all over the skin's surface, or confined to just one area. The medical term for itching is pruritus.

Description

Itching instinctively leads most people to scratch the affected area. Different people can tolerate different amounts of itching, and anyone's threshold of tolerance can be changed due to **stress**, emotions, and other factors. In general, itching is more severe if the skin is warm, and if there are few distractions. This is why people tend to notice itching more at night.

Causes and symptoms

The biology underlying itching is not fully understood. It is believed that itching results from the interactions of several different chemical messengers. Although itching and **pain** sensations were at one time thought to be sent along the same nerve pathways, researchers reported the discovery in 2003 of itch-specific nerve pathways. Nerve endings that are specifically sensitive to itching have been named pruriceptors.

Research into itching has been helped by the recent invention of a mechanical device called the Matcher, which electrically stimulates the patient's left hand. When the intensity of the stimulation equals the intensity of itching that the patient is experiencing elsewhere in the body, the patient stops the stimulation and the device automatically records the measurement. The Matcher was found to be sensitive to

immediate changes in the patient's perception of itching as well as reliable in its measurements.

Stress and emotional upset can make itching worse, no matter what the underlying cause. If emotional problems are the primary reason for the itch, the condition is known as psychogenic itching. Some people become convinced that their itch is caused by a parasite; this conviction is often linked to burning sensations in the tongue, and may be caused by a major psychiatric disorder.

Generalized itching

Itching that occurs all over the body may indicate a medical condition such as **diabetes mellitus**, **liver disease**, kidney failure, **jaundice**, thyroid disorders (and rarely, cancer). Blood disorders such as leukemia, and lymphatic conditions such as Hodgkin's lymphoma may sometimes cause itching as well.

Some people may develop an itch without a rash when they take certain drugs (such as **aspirin**, codeine, cocaine); others may develop an itchy red "drug rash" or **hives** because of an allergy to a specific drug. Some medications given to cancer patients may also cause itching.

Itching also may be caused when any of the family of hookworm larvae penetrate the skin. This includes swimmer's itch and creeping eruption caused by cat or dog hookworm, and ground itch caused by the "true" hookworm.

Many skin conditions cause an itchy rash. These include:

- Atopic dermatitis
- Chickenpox
- Contact dermatitis
- Dermatitis herpetiformis (occasionally)
- Eczema
- Fungus infections (such as athlete's foot)
- Hives (urticaria)
- Insect bites
- Lice
- Lichen planus
- Neurodermatitis (lichen simplex chronicus)
- Psoriasis (occasionally)
- Scabies

On the other hand, itching all over the body can be caused by something as simple as bathing too often, which removes the skin's natural oils and may make the skin too dry and scaly.

Localized itching

Specific itchy areas may occur if a person comes in contact with soap, detergents, and wool or other rough-textured, scratchy material. Adults who have **hemorrhoids**, anal fissure, or persistent **diarrhea** may notice itching around the anus (called pruritus ani). In children, itching in this area is most likely due to worms.

Intense itching in the external genitalia in women (pruritus vulvae) may be due to **candidiasis**, hormonal changes, or the use of certain spermicides or vaginal suppositories, ointments, or deodorants.

It is also common for older people to have dry, itchy skin (especially on the back) for no obvious reason. Younger people also may notice dry, itchy skin in cold weather. Itching is a common complaint during **pregnancy**.

Diagnosis

Itching is a symptom that is quite obvious to the patient. Someone who itches all over should seek medical care. Because itching can be caused by such a wide variety of triggers, a complete physical exam and medical history will help diagnose the underlying problem. A variety of blood and stool tests may help determine the underlying cause.

Treatment

Antihistamines such as diphenhydramine (Benadryl) can help relieve itching caused by hives, but will not affect itching from other causes. Most antihistamines also make people sleepy, which can help patients sleep who would otherwise be awake from the itch.

Specific treatment of itching depends on the underlying condition that causes it. In general, itchy skin should be treated very gently. While scratching may temporarily ease the itch, in the long run scratching just makes it worse. In addition, scratching can lead to an endless cycle of itch–scratch–more itching.

To avoid the urge to scratch, a person can apply a cooling or soothing lotion or cold compress when the urge to scratch occurs. Soaps are often irritating to the skin, and can make an itch worse; they should be avoided, or used only when necessary.

Creams or ointments containing cortisone may help control the itch from insect bites, **contact dermatitis** or **eczema**. Cortisone cream should not be applied to the face unless a doctor prescribes it.

WWW.BOOKBAZ.IR

KEY TERMS

Atopic dermatitis—An intensely itchy inflammation often found on the face of people prone to allergies. In infants and early childhood, it is called infantile eczema.

Creeping eruption—Itchy, irregular, wandering red lines on the foot made by burrowing larvae of the hookworm family and some roundworms.

Dermatitis herpetiformis—A chronic very itchy skin disease with groups of red lesions that leave spots behind when they heal. It is sometimes associated with cancer of an internal organ.

Eczema—A superficial type of inflammation of the skin that may be very itchy and weeping in the early stages; later, the affected skin becomes crusted, scaly, and thick. There is no known cause.

Hodgkin's lymphoma—A type of cancer characterized by a slowly-enlarging lymph tissue; symptoms include generalized itching.

Lichen planus—A noncancerous, chronic itchy skin disease that causes small, flat purple plaques on wrists, forearm, ankles.

Neurodermatitis—An itchy skin disease (also called lichen simplex chronicus) found in nervous, anxious people.

Pruriceptors—Nerve endings specialized to perceive itching sensations.

Pruritus—The medical term for itching.

Psoriasis—A common, chronic skin disorder that causes red patches anywhere on the body. Occasionally, the lesions may itch.

Scabies—A contagious parasitic skin disease characterized by intense itching.

Swimmer's itch—An allergic skin inflammation caused by a sensitivity to flatworms that die under the skin, causing an itchy rash.

Probably the most common cause of itching is dry skin. There are a number of simple things a person can do to ease the annoying itch:

- do not wear tight clothes
- avoid synthetic fabrics
- do not take long baths
- wash the area in lukewarm water with a little baking soda
- for generalized itching, take a lukewarm shower
- take a lukewarm oatmeal (or Aveeno) bath for generalized itching
- apply bath oil or lotion (without added colors or scents) right after bathing

Itching may also be treated with whole-body medications. In addition to antihistamines, some of these systemic treatments include:

- tricyclic antidepressants
- sedatives or tranquilizers
- such selective serotonin reputake inhibitors as paroxetine (Paxil) and sertraline (Zoloft)
- binding agents (such as cholestyramine, which relieves itching associated with kidney or liver disease)
- aspirin
- cimetidine

People who itch as a result of mental problems or stress should seek help from a mental health expert.

Alternatives

A well-balanced diet that includes carbohydrates, fats, **minerals**, proteins, **vitamins**, and liquids will help to maintain skin health. Capsules that contain eicosapentaenoic acid, which is obtained from herring, mackerel, or salmon, may help to reduce itching. **Vitamin A** plays an important role in skin health. **Vitamin E** (capsules or ointment) may reduce itching. Patients should check with their treating physician before using supplements.

Homeopathy has been reported to be effective in treating systemic itching associated with hemodialysis.

Baths containing oil with milk or oatmeal are effective at relieving localized itching. Evening primrose oil may soothe itching and may be as effective as **corticosteroids**. Calendula cream may relieve short-term itching. Other herbal treatments that have been recently reported to relieve itching include sangre de drago, a preparation made with sap from a South American tree; and a mixture of honey, olive oil, and beeswax.

Distraction, **music therapy**, relaxation techniques, and visualization may be useful in relieving itching. Ultraviolet **light therapy** may relieve itching associated with conditions of the skin, kidneys, blood, and

gallbladder. There are some reports of the use of **acupuncture** and transcutaneous electrical nerve stimulators (TENS) to relieve itching.

Prognosis

Most cases of itching go away when the underlying cause is treated successfully.

Prevention

There are certain things people can do to avoid itchy skin. Patients who tend toward itchy skin should:

- Avoid a daily bath
- Use only lukewarm water when bathing
- Use only gentle soap
- Pat dry, not rub dry, after bathing, leaving a bit of water on the skin
- Apply a moisture-holding ointment or cream after the bath
- Use a humidifier in the home

Patients who are allergic to certain substances, medications, and so on can avoid the resulting itch if they avoid contact with the allergen. Avoiding insect bites, bee stings, **poison ivy** and so on can prevent the resulting itch. Treating sensitive skin carefully, avoiding overdrying of the skin, and protecting against diseases that cause itchy **rashes** are all good ways to avoid itching.

Japanese encephalitis

Definition

Japanese encephalitis is an infection of the brain caused by a virus. The virus is transmitted to humans by mosquitoes.

Demographics

Many of these areas are in Asia, including Japan, Korea, China, India, Thailand, Indonesia, Malaysia, Vietnam, Taiwan, and the Philippines. Areas where the disease-causing arbovirus is always present are referred to as being endemic for the disease. In such areas, blood tests will reveal that more than 70% of all adults have been infected at some point with the arbovirus.

Because the virus that causes Japanese encephalitis is carried by mosquitoes, the number of people infected increases during those seasons when mosquitoes are abundant. This tends to be in the warmest, rainiest months. In addition to humans, wild birds and pigs are susceptible to infection with this arbovirus. Because the specific type of mosquito carrying the Japanese encephalitis arbovirus frequently breeds in rice paddies, the disease is considered to be primarily a rural problem.

About 45,000 cases of Japanese encephalitis are reported each year; however, the disease is thought to be seriously underreported. The disease is about 1.5 times more common in men than in women, possibly because men are likely to spend more time outdoors in areas where the disease is endemic. Cases in the United States are exceedingly rare (less than one case per year) and usually occur in military personnel or other Americans who have returned home after living in affected areas.

Description

The virus that causes Japanese encephalitis is called an arbovirus, which is an arthropod-borne virus. Mosquitoes are a type of arthropod. Mosquitoes in a number of regions carry this virus. The virus is passed to humans when the mosquitoes bite them. The disease cannot be passed directly from human to human, nor can it be passed directly from animals infected with the virus to human. Not all infections cause severe symptoms; in many cases the only symptoms are a **fever** and **headache**. In areas where the virus is common, most people become infected by the time they are young adults.

Causes and symptoms

The virus is transferred to a human when an infected mosquito sucks that person's blood. Once in the body, the virus travels to various glands where it multiplies. The virus can then enter the bloodstream. Ultimately, the virus settles in the brain, where it causes serious problems.

The time from becoming infected to starting to show symptoms (incubation period) usually is 5–15 days. Serious cases of Japanese encephalitis begin abruptly with fever, severe headache, nausea, and **vomiting**. As the tissue covering the brain and spinal cord (the meninges) becomes infected and swollen, the patient will develop a stiff and painful neck. By day two or three, the patient begins to suffer the effects of swelling in the brain. These effects include:

- problems with balance and coordination
- paralysis of some muscle groups
- tremors
- seizures
- lapses in consciousness
- a stiff, mask-like appearance of the face

The patient becomes dehydrated and loses weight. If the patient survives the illness, the fever will decrease by about day seven and the symptoms will begin to improve by about day 14. Other patients will continue to have extremely high fevers and their symptoms will

KEY TERMS

Encephalitis—A swelling of the brain, potentially causing serious brain damage.

Endemic—Naturally and consistently present in a certain geographical region.

get worse. In these cases, **coma** and then death occur in 7–14 days. Many patients who recover have permanent disabilities due to brain damage.

Diagnosis

Most diagnostic techniques for Japanese encephalitis do not yield results very quickly. The diagnosis is made primarily on the basis of the patient's symptoms and the knowledge of the kinds of illnesses endemic to a particular geographic region.

Tests

Immunofluorescence tests, where special viral markers react with human antibodies that have been tagged with a fluorescent chemical, are used to verify the disease. However, these results tend to be unavailable until week two of the infection. Other tests involve comparing the presence and quantity of particular antibodies in the blood or spinal fluid during week one with those present during week two of the illness.

Treatment

There are no treatments available to stop or slow the progression of Japanese encephalitis. Only the symptoms of each patient can be treated. Fluids are given to decrease **dehydration** and medications are given to decrease fever and **pain**. Medications are available to attempt to decrease brain swelling. Patients in a coma may require mechanical assistance with breathing.

Prognosis

While the majority of people infected with arbovirus never become seriously sick, those who develop Japanese encephalitis become very ill. Death ranges can range from 30% to 60%. A variety of long-term problems may haunt those who recover from the illness. These problems include:

- movement difficulties where the arms, legs, or body jerks or writhes involuntarily
- shaking
- paralysis
- inability to control emotions
- loss of mental abilities
- mental disturbances, including schizophrenia (which may affect as many as 75% of Japanese encephalitis survivors)

Young children are most likely to have serious, long-term problems after an infection.

Prevention

Two different vaccines are available for immunization against Japanese encephalitis. A three-dose vaccine is available for Japanese encephalitis and is commonly given to young children in areas where the disease is endemic. A two-dose vaccine can be give to people age 17 and older. Both vaccines are given over the period of a 28–30 days and should be completed at least 7–10 days before entering an area where the Japanese encephalitis virus is common.

The vaccine is not 100% effective, thus controlling the mosquito population with insecticides is an essential preventive measure. Visitors to regions with high rates of Japanese encephalitis should take precautions (like using mosquito repellents such as DEET and sleeping under a bed net) to avoid contact with mosquitoes.

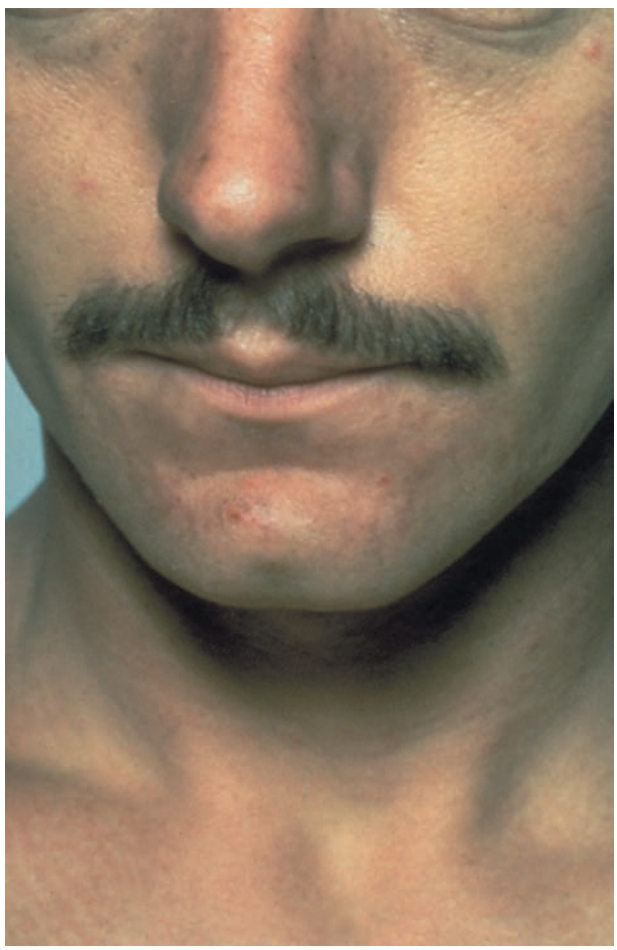
Jaundice

Definition

Jaundice is a condition in which the skin and whites of the eyes turn yellowish from increased levels of a waste product called bilirubin. Although jaundice is common in newborn infants, at any time after the first few weeks of life it can be a symptom of a serious underlying condition. Jaundice is sometimes called hyperbilirubinemia or icterus from the Greek word for the condition.

Demographics

Newborn jaundice affects more than half of all full-term newborns and 80% of premature newborns within the first few days of life, although only about 10% of newborns require treatment. Jaundice is often more severe in Asian and Native American infants. **Biliary atresia**, a congenital defect in the bile ducts that can cause severe hyperbilirubinemia in otherwise healthy infants, occurs in about one in every 15,000 live births and girls are slightly more at risk than boys.



This patient suffers from obstructive jaundice, which is often caused by gallstones. *(Custom Medical Stock Photo, Inc.)*

Description

Bilirubin is a yellow pigment that is formed from the breakdown of hemoglobin—the oxygen-carrying protein in red blood cells (RBCs). RBCs normally are removed from the blood and broken down in the spleen and other parts of the body after about 120 days in circulation. About 1% of RBCs are normally broken down and replaced each day. Bilirubin is carried to the liver where it is attached or conjugated to another molecule and added to bile. Conjugated bilirubin is known as direct or soluble bilirubin and unconjugated bilirubin is known as indirect or insoluble bilirubin.

Bile that is formed in the liver passes into the network of hepatic bile ducts, which join to form a single tube. One branch of this tube carries bile to the gallbladder where it is stored and concentrated. When food enters the stomach, the gallbladder is stimulated to release bile to the intestines through the common bile duct. Before the common bile duct reaches the intestines, it is joined by a duct from the pancreas. Bile and pancreatic juice enter the intestine through a valve called the ampulla of Vater. After entering the intestine, bile and pancreatic secretions assist in digestion and bile is excreted in the stool. However if bilirubin accumulates in the blood rather than being excreted, it discolors tissues, turning the skin and whites of the eyes yellow.

Risk factors

Risk factors for newborn jaundice include:

- Asian or Native American parentage
- a parent or sibling who had high bilirubin levels at birth
- maternal diabetes
- premature birth
- induced labor
- birth at a high altitude
- bruising during birth
- excessive weight loss during the first few days after birth

Causes and symptoms

Although jaundice is always caused by a buildup of bilirubin in the blood and tissues, there are many

different causes for this buildup. The causes can be divided into three categories based on where they occur in the bilirubin cycle: before, in, or after the liver—pre-hepatic, hepatic, or post-hepatic.

The pre-hepatic cause of jaundice is hemolysis—the death of RBCs at a faster-than-normal rate, which releases hemoglobin and causes bilirubin to accumulate. The many causes of hemolysis include:

- Malaria. The malaria parasite develops inside RBCs and destroys them when it matures. Bilirubin can enter the urine in sufficient quantities to cause "blackwater fever," which is often lethal.
- Certain drugs. Hemolysis is a rare but sudden side effect of some antibiotics, anti-tuberculosis medications, drugs that regulate heartbeat, and levodopa for treating **Parkinson's disease**.
- Certain drugs in combination with an inherited deficiency in the enzyme glucose-6-phosphate dehydrogenase (G6PD). G6PD deficiency affects more than 200 million people worldwide. Some of the drugs listed above, as well as certain others, especially vitamins C and K and anti-malarial medications such as quinine, can cause hemolysis in people with G6PD deficiency.
- Poisons. Snake and spider venoms, certain bacterial toxins, copper, and some organic industrial chemicals cause hemolysis by directly attacking RBC membranes.
- Artificial heart valves. The inflexible moving parts of artificial heart valves damage RBCs.
- Hereditary RBC disorders. Sickle cell disease, which results in abnormal hemoglobin, spherocytosis, which weakens the outer membrane of RBCs, and various other inherited defects that affect the internal chemistry of RBCs can all cause hemolysis.
- Enlargement of the spleen. The spleen filters the blood and destroys old RBCs. If it becomes enlarged, healthy RBCs also are filtered out resulting in hemolysis. A wide variety of conditions can cause enlargement of the spleen.
- Diseases of the small blood vessels. As the RBCs move through diseased capillaries they can be damaged by rough surfaces on the inside of vessel walls.
- Immune reactions. The immune system can produce antibodies that destroy RBCs.
- Blood transfusions. Hemolysis can result from a transfusion with an incompatible blood type.
- Kidney failure and other serious diseases. Several diseases cause defective blood coagulation that destroys RBCs.
- Erythroblastosis fetalis. This results from too many immature RBCs (erythroblasts) in a newborn, usually because of a blood factor incompatibility between the mother and infant that causes maternal antibodies to destroy the newborn's RBCs.

Newborn jaundice results from both pre-hepatic and hepatic sources of excess bilirubin. At birth the newborn immediately begins converting from fetal to adult-type hemoglobin. The removal of the fetal hemoglobin can overload the immature liver for a week or two after birth, resulting in excess bilirubin and jaundice. Bilirubin gives a newborn's stools their yellow color. Jaundice usually appears first on the face, on the third or fourth day after birth, and progresses downward to the chest, abdomen, legs, and feet. If newborn feeding is delayed for any reason, such as illness, a digestive tract problem, or low fluid intake due to inefficient **breastfeeding**, the infant produces fewer stools, which can result in critically high blood levels of bilirubin and severe jaundice.

Jaundice at birth or within the first 24 hours can be a sign of abnormal jaundice, which can be very dangerous, particularly in preterm or unhealthy newborns. **Erythroblastosis fetalis** is the most common cause of abnormal newborn jaundice.

Other causes of hepatic jaundice include a variety of liver diseases in which the damaged organ cannot to keep up with bilirubin processing. These hepatic causes of jaundice include:

- starvation
- circulating (systemic) infections
- certain medications
- hepatitis
- cirrhosis
- hereditary defects in liver chemistry, including Gilbert's syndrome and Crigler-Najjar syndrome

Obstructive jaundices are post-hepatic forms caused by failure of soluble bilirubin to reach the intestines after leaving the liver. The most common cause of obstructive jaundice is **gallstones** in the ducts of the biliary system. Other causes of obstructive jaundice include:

- birth defects such as biliary atresia or infections that damage the bile ducts
- drugs
- cancers
- physical injury
- certain drugs—and rarely, pregnancy—that simply cause the bile in the ducts to stop flowing

Jaundice has no symptoms other than discoloration of the skin and eyes and is usually harmless, although the underlying condition may cause other symptoms and complications. However if unconjugated bilirubin

WWW.BOOKBAZ.IR

KEY TERMS

Ampulla of Vater—The widened portion of the duct through which bile and pancreatic juices enter the intestine. Ampulla is a Latin word for a bottle with a narrow neck that opens into a wide body.

Anemia—A deficiency in hemoglobin, red blood cells, or total blood volume.

Bile—A liquid secreted by the liver and passed through ducts to the small intestine where it aids in the digestion and absorption of fats.

Biliary atresia—The underdevelopment or absence of bile ducts.

Biliary system/bile ducts—The gall bladder and the system of tubes that carries bile from the liver into the intestine.

Bilirubin—A reddish-yellow pigment that is a breakdown product of hemoglobin and is excreted by the liver into the bile.

Cirrhosis—Disruption of liver function due to damage from chronic progressive disease.

Crigler-Najjar syndrome—A moderate to severe form of hereditary jaundice.

Erythroblastosis fetalis—A disorder of newborn infants marked by a high level of immature red blood cells (erythroblasts).

Gilbert's syndrome—A mild hereditary form of jaundice.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency—A hereditary disorder that, in combination with certain medications, can lead to episodes of hemolytic anemia.

Hemoglobin—The red substance in blood cells that carries oxygen.

Hemolysis—The destruction or breakdown of red blood cells.

Hepatic—Referring to the liver.

Hepatitis—Inflammation of the liver or the disease or condition causing liver inflammation.

Hyperbilirubinemia—An excess of bilirubin in the blood.

Icterus—Jaundice.

Microangiopathic—Pertaining to disorders of the small blood vessels.

Pancreas—The organ beneath the stomach that produces digestive juices, insulin, and other hormones.

Sickle cell disease—A hereditary defect in hemoglobin that changes the shape of red blood cells.

Splenectomy—Surgical removal of the spleen.

reaches the newborn brain, it can cause permanent damage. Prolonged jaundice can also upset the balance of chemicals in the bile and cause the formation of stones.

Diagnosis

Examination

Jaundice is usually evident from the yellowish tint of the eyes and complexion. All newborns are examined under good light for signs of jaundice. The physician will feel (palpate) the liver and spleen to check for enlargement and evaluate any abdominal **pain**. The location and severity of abdominal pain and the presence or absence of **fever** help distinguish between hepatic and obstructive jaundice.

Tests

Blood tests measure the levels of total and/or conjugated bilirubin in the blood. Total bilirubin in the blood serum is normally between 0.3 milligrams (mg) per deciliter (dL) and 1.9 mg/dL. Conjugated or direct bilirubin is normally 0–0.3 mg/dL. Jaundice occurs when the total bilirubin level rises to 3 mg/dL or higher. It may be necessary to repeatedly measure bilirubin levels in jaundiced newborns because of the danger of insoluble bilirubin reaching the brain. An instrument called a bilirubinometer can be held against the infant's skin to assess the level of jaundice, eliminating the need for blood tests.

Additional tests may include:

- blood cell counts to detect anemia
- tests for blood-clotting function
- tests for excess destruction of RBCs
- blood tests to assess liver function
- urine and stool samples to check for signs of bacterial or viral infection

Procedures

Various procedures may be used to diagnose a disorder underlying jaundice:

- Sometimes a bone marrow biopsy is necessary to diagnose blood-formation disorders.

- Ultrasound or a nuclear scan may be used to evaluate the spleen.
- A liver biopsy may be necessary to diagnose liver disease. A thin needle is used to remove a tiny core of liver tissue, which is sent to the laboratory for microscopic examination.
- Computed tomography (CT) or magnetic resonance imaging (MRI) scans are very useful for imaging certain conditions such as cancers in and around the liver or gallstones in the common bile duct.
- Various imaging techniques can be used to diagnose diseases of the biliary system. X rays for obtaining functional as well as anatomical information are taken one day after swallowing a contrast agent that is secreted into the bile. Alternatively contrast dye can be injected directly into the bile ducts, through a thin needle pushed into the liver or through a scope that is passed through the stomach to inject the dye into the ampulla of Vater.

Treatment

Jaundice itself is treated only in newborns with dangerously high bilirubin levels. In the past it was necessary to exchange most of the infant's blood. Now the newborn can be fitted with eye protection and placed under a high-intensity, cool, blue-fluorescent light. The light is absorbed by the bilirubin and converts it into a harmless form than can be excreted in the bile and urine. Other **phototherapy** methods—such as a fiber optic bilirubin blanket—incorporate the light into a blanket so that the child can be breastfed during treatment or treated at home. Frequent feedings lead to more frequent stools, which reduces the reabsorption of bilirubin from the intestines into the blood. The infant also may be given additional fluids, possibly intravenously, to help remove bilirubin.

Obstructive jaundice frequently requires surgery. Surgery for biliary atresia must be performed within the first few weeks of life to prevent fatal liver damage. A common technique is to stitch an open piece of intestine over a bare patch of liver. Tiny bile ducts in that part of the liver will begin to discharge their bile into the intestine and pressure from the obstructed ducts elsewhere will release in that direction. As the bile flow increases, the ducts grow to accommodate it until all of the bile is redirected through the open pathways.

There are a variety of treatments for other conditions underlying jaundice:

- Any medications that are causing hemolysis or arresting the flow of bile are stopped immediately.
- Hemolytic diseases are treated, if at all, with medications and blood transfusions, except in the case of an enlarged spleen. Surgical removal of the spleen (splenectomy) can sometimes cure hemolytic anemia.
- Although there are no specific cures for most liver diseases, the liver can recover from even severe damage and regenerate from only a small remnant of original tissue.

Prognosis

Prognosis depends on the condition underlying the jaundice. Normal newborn jaundice is not harmful and disappears after one–two weeks. In cases of severe newborn jaundice, phototherapy usually returns bilirubin levels to normal within a few days. Infants with a duct obstruction within the liver itself usually require a liver transplant by the age of two.

Prevention

Prevention of jaundice involves preventing the underlying condition:

- Malaria in tropical or subtropical countries can often be prevented by precautions such as bed nets treated with insecticides or mosquito repellants and prophylactic drugs such as mefloquine.
- Hemolytic side effects from medications can be minimized with early detection and immediate cessation of the drug.
- G6PD-deficiency hemolysis can be prevented by testing patients before administering the causative drugs.
- Erythroblastosis fetalis can be prevented by treating an Rh-negative mother with a gamma-globulin solution called RhoGAM if there is a possibility that she is developing antibodies against her baby's blood.

The American Academy of Pediatrics recommendations for identifying and managing **neonatal jaundice** include:

- assessing all newborns for risk of severe jaundice, including measuring bilirubin levels before hospital discharge
- a follow-up visit within three to five days after birth when bilirubin levels are likely to peak
- breastfeeding a newborn at least eight to 12 times per day, since effective breastfeeding significantly reduces the risk of hyperbilirubinemia

Jaw wiring

Definition

Jaw wiring, also known as maxillomandibular fixation, is a surgical procedure where metal pins and wires are anchored into the jaw bones and surrounding tissues to keep the jaw from moving.

Purpose

Sports injuries, automobile accidents, falls, or fistfights are a few of the situations where the jaw might be fractured or broken. In these cases, jaw wiring may be necessary to keep the bones aligned and stable while the jaw heals. The presence of cancer or other diseased tissues may make removal and reconstruction of the jaw necessary. Wiring the jaws shut has been used in the past as a weight loss aid in cases of extreme **obesity** where other treatments had failed, although this procedure is rarely used for that purpose today.

Precautions

Traumatic injuries to the face can cause damage to facial nerves and salivary glands and ducts. These injuries can also leave **scars** that may require additional surgery to correct.

Description

Jaw wiring surgery can be performed by an oral or maxillofacial surgeon (a specially trained dentist), or by an otolaryngologist (a doctor specializing in surgeries of the head and neck). The procedure may be done in a medical or dental office if the office is staffed and equipped to handle this type of surgery. More often, this surgery is performed in a hospital or medical center surgical area. If jaw wiring is required due to an injury, the surgeon may set the fracture immediately before swelling sets in. It is also possible to wait (up to several weeks) until the swelling goes down and some of the soft tissue injuries have healed, prior to wiring the jaw fracture.

The surgeon realigns the fractured bones. Every effort is made to restore the shape and appearance of the original jaw line. If any teeth were damaged, repair or replacement may be done at the same time. Small incisions may be made through the skin and surrounding tissue so the pins and wires can be set into the jawbone to hold the fracture together. To prevent the lower jaw from moving during healing, pins and wires may be inserted into the top jaw, as well. The upper and lower jaws are then wired together in order to stabilize the fracture.

As with other types of bone **fractures**, the jaw may take several weeks to heal. Another type of jaw **immobilization** that has been developed more recently, rigid fixation uses small metal plates and screws rather than pins and wires to secure the jaw bones. The main benefit of this technique is that the jaws do not have to be wired shut, allowing the patient to return to a more normal lifestyle sooner.

KEY TERMS

Oral and maxillofacial surgeon—A dentist who is trained to perform surgery to correct injuries, defects, or conditions of the mouth, teeth, jaws, and face.

Otolaryngologist—A doctor who is trained to treat injuries, defects, or conditions of the head and neck.

Preparation

X rays of the fractured area may be taken prior to surgery. Depending on the extent of the facial injury or condition to be corrected, the patient may receive a sedative for relaxation, a local anesthetic drug to numb the area, and/or an anesthetic agent to induce unconsciousness prior to the surgery.

Aftercare

A patient whose jaw has been wired will not be able to eat solid foods for several weeks. In order for the bone and surrounding tissues to heal, it is important to maintain adequate **nutrition**. A liquid diet that can be consumed through a straw, will be required. Soft, precooked foods can be liquefied in a blender, however, it may be difficult for the patient to consume adequate calories, protein, **vitamins**, and **minerals** with this type of diet. Liquid diet formulas may be a good alternative. The patient will also have to be taught how to care for the mouth, teeth, and injured area while the wires are in place.

Risks

It is possible that scarring may occur due to the need to make small incisions in the skin in order to insert the wires. With any surgical procedure, there are risks associated with the anesthetic drugs used and the possibility of infection. If there is a risk that the patient may vomit, the jaw wiring may pose a **choking** hazard. It may be recommended that wire cutters be kept available in case the wires need to be cut in an emergency situation.

Jet lag

Definition

Jet lag, also sometimes called desynchronosis, is a physiological condition marked by **fatigue**, **insomnia**, and irritability that is caused by air travel—usually going from east to west or from west to east—through many changing time zones. It is classified as a circadian rhythm sleep disorder because it alters (disrupts) the natural circadian rhythm ("internal body clock") in humans. The temporary condition is primarily caused by air travel across several time zones, but can also be caused by shift work or other factors. Jet lag comes about from the inability of the internal body clock to adjust quickly enough to drastic changes in the normal sleep and wake cycle. Usually it lasts only for a few days but it can last longer depending on the length of travel and the steps taken to counter it.

Generally, jet lag lasts longer when traveling west to east, than it does when flying east to west. A general relationship is: jet lag lasts two-thirds of a day for each time zone crossed while flying eastward, and lasts one-half of a day for each time zone crossed while heading westward. Thus, flying westward across two time zones would cause jet lag for about one day for the average air traveler.

Demographics

The condition called jet lag can occur in air travelers of all ages and genders when they travel across several time zones. Prior research does not support the contention that it affects those of one age more than another. However, medical studies do show that women are at higher risk than men for getting jet lag, primarily due to the higher levels of estrogen in women's bodies. Exposure to natural light after completing

WWW.BOOKBAZ.IR

a long trip usually helps to accelerate the adaption process, especially when travel is over three or more time zones.

Description

The natural circadian rhythm in humans is located in the suprachiasmatic nuclei at the base of the hypothalamus, all within the brain. The suprachiasmatic nuclei contain receptors that receive melatonin, which is manufactured in the pineal gland. Melatonin is released based on the amount of darkness or light in one's local environment. More of it is released during the night and less during the day. Consequently, a person's sleep and wake cycle (or "internal body clock") is established by this relationship with the manufacture and release of melatonin based on dark and light cycles.

Over millions of years living organisms have become accustomed to periods of night and day alternating at set intervals. Thus, they (both plants and animals) have a tendency to operate on an approximate 24-hour cycle based on the cycles of sunlight and darkness. Most of the human body's regulating hormones follow this cycle, known as circadian rhythm. The word circadian comes from the Latin, *circa*, meaning about, and *dies*, meaning day. These cycles are not exactly 24 hours long, hence the "circa." Each chemical has its own cycle of highs and lows, interacting with and influencing the other cycles. Characteristics such as body temperature, sleepiness, thyroid function, growth hormone, metabolic processes, adrenal hormones, and the sleep hormone melatonin cycle with daylight. A direct connection exists between the retina (where light hits the back of the eye) and the part of the brain that controls all these hormones. Artificial light has some effect, but sunlight has much more.

When people are without clocks in a compartment that is completely closed to sunlight, most of them fall into a circadian cycle of about 25 hours. Normally, all the regulating chemicals follow one another in order like threads in a weaving pattern. Every morning the sunlight resets the cycle, stimulating the leading chemicals and thus compensating for the difference between the 24-hour day and the 25-hour innate rhythm.

When traveling through a number of time zones, most people reset their rhythms within a few days, demonstrating the adaptability of the human species. Some people, however, have upset rhythms that last much longer. Whatever the period of adjustment, the experience can cause biological and brain wave activity that tries to cope with the new situation. During this coping period, the human undergoing jet lag may feel irritable, fatigue, and disorientiation.

Causes and symptoms

Jet lag is primarily caused by the direction of travel and the number of time zones crossed. However, it can also be affected by a person's ability (or inability) to sleep just before, during, and just after traveling; tolerance (or intolerance) to air travel, and the similarity (or difference) of the natural day-and-night cycle between the departing and arriving locations.

Flying north or south, such as from Chicago, Illinois, to Houston, Texas, does not generally cause jet lag because a time zone has not been changed and periods of night and day have not changed. However, flying east or west, such as from New York City to Los Angeles, does cause jet lag in people. Traveling west to east is generally considered to be more disruptive than travel from east to west. This difference occurs because the circadian cycle is pushed forward (earlier time zone) rather than back (later time zone) when traveling west to east as compared to traveling east to west. Thus, as people travel to places where daylight and darkness are different from what they are used to, then the body's clock becomes disrupted and jet lag occurs. However, flying north or south can cause jet jag when travel changes the normal period of darkness to daytime and the normal period of sunlight to night–time, such as when traveling from Denver, Colorado, in the Northern Hemisphere, to Lima, Peru, in the Southern Hemisphere.

When jet lag occurs, the body's natural pattern is upset. Such things as sleep, body temperature, and hormone regulation are no longer in synchronization to the new environment. Consequently, it takes the human body a period of adjustment to realign itself to its new locality. Traveling through a few time zones at a time is not as disruptive to circadian rhythms as traveling around the world can be. The foremost symptom of jet lag is altered sleep pattern—sleepiness during the day, and insomnia during the night. Jet lag may also include **indigestion** and trouble concentrating. Individuals afflicted by jet lag will alternate in and out of a normal day-night cycle.

It may take one person several days to adjust to a new time zone, while another person may not even experience any problems. Generally, one or two new time zones will not cause problems, but more than that number will usually cause some symptoms identified with jet lag.

Symptoms associated with jet lag include: fatigue, insomnia, irritability, **anxiety** or mild depression, nausea, **headache**, disorientation, loss of appetite, **diarrhea** or **constipation** (along with general gastrointestinal disturbances), reduced ability (or inability) to perform

common physical and mental tasks, and decreased ability to concentrate. Disorientation and fatigue are the two most common symptoms of jet lag.

Shift work is another cause of what is called jet lag, although it has nothing to do with flying in an airplane. Many people work shifts that are not the customary time during the daylight hour, which is usually called first shift (or day work). They may work a second shift from late in the afternoon to the middle of the night, say, from 5 P.M. to 2 A.M. In another scenario, a person might work a third shift from the middle of the night to early in the morning, for example, from midnight to 8 a.m. In either case, such changes in the normal schedule of being awake during sunlight hours and sleeping during darkness can cause symptoms very similar to jet lag. These symptoms can be worsened when shift work is changed over a week, for instance, five days of working third shift but a two-day weekend where the worker tries to resume a normal life.

Treatment

Current treatments

In cases of short-term insomnia triggered by jet lag, a physician may recommend over-the-counter (OTC) sleeping pills or prescription medication. These medicines may help to counter the biological imbalance caused by jet lag. However, they can cause adverse side effects. Thus, such medication should only be taken under the guidance of a healthcare professional.

Investigational treatments

A medication that is considered investigational is a melatonin agonist known as LY 156735 (PD–6735). An agonist is a drug that stimulates activity at cell receptors that are normally stimulated by such naturally occurring substances as melatonin. LY 156735 was found to speed up the re–adaptation time of volunteer subjects following a simulated nine–hour time shift. As of 2014, it is still under development as a treatment for jet lag, insomnia, and other such **sleep disorders**. Melatonin is thought to increase the ability to drift off to sleep but it not believed to help in increasing the amount of sleep one gets. It is not regulated by the Food and Drug Administration (FDA) but may be bought at health food stores and other such retail stores. Consult a medical professional before trying such drugs.

Another area of research involves the genes that encode the proteins governing circadian rhythms. It is known that differences among individuals in adaptability to time zone changes are to some extent genetically determined. Targeting the genes that affect this adaptability may yield new treatments for jet lag and other disorders of circadian rhythm. These medical studies are still underway.

Alternatives

Exposure to bright morning sunlight cures jet lag after a few days in most people. A few will have prolonged sleep phase difficulties. For these, a curious treatment has achieved success. By forcing one's self into a 27-hour day, complete with the appropriate stimulation from bright light, all the errant chemical cycles will be able to catch up during one week.

When selecting an international flight, individuals should try to arrange an early evening arrival in their destination city. When an individual is traveling to a destination in the east, he or she can try going to bed and waking up a few hours earlier several days before their flight. If travel is to the west, going to bed and waking up later than usual can help the body start to adjust to the upcoming time change.

The following precautions taken during an international flight can help to limit or prevent jet lag:

- Stay hydrated. Drink plenty of water and juices to prevent dehydration. Beverages and foods with caffeine should be avoided because of their stimulant properties. Alcohol should also be avoided.
- Stretch and walk. As much movement as possible during a flight helps circulation, which moves nutrients and waste through the body and aids in elimination.
- Stay on time. Set watches and clocks ahead to the time in the destination city to start adjusting to the change.
- Eat a light snack upon arrival at the destination.
- Get as much natural sunlight as possible to help reset one's biological clock. Do not stay inside because avoidance of sunlight makes matters worse.
- Sleep smart. Draw the shade and sleep during the evening hours in the destination city, even if it is still daylight outside of the airplane. Earplugs and sleep masks may be helpful in blocking noise and light. Many airlines provide these items on international flights.
- Dress comfortably. Wear or bring comfortable clothes that will make sleeping during the flight easier.

Once arriving in their destination city, individuals should spend as much time outdoors in the sunlight as possible during the day to reset their internal clock and lessen the symptoms of jet lag. Bedtime should be postponed until at least 10 P.M., with no daytime naps. If a daytime nap is absolutely necessary, it should be limited to no more than two hours.

WWW.BOOKBAZ.IR

KEY TERMS

Agonist—A medication that has an affinity for and stimulates the activity of cell receptors that are normally stimulated by naturally occurring substances, including melatonin.

Circadian—Pertaining to biological rhythms occurring at approximately 24-hour intervals. Jet lag is caused by a disruption of the human body's circadian clock.

Hormone—A chemical made in one part of the body that has an effect on another part.

Melatonin—A hormone that helps to regulate circadian rhythms.

To promote a restful sleeping environment in a hotel setting, individuals should request that the hotel desk hold all phone calls. Because sleeping in too late can also prolong jet lag, an early wake-up call should be requested if an alarm clock is not available. If the hotel room is noisy, a portable white noise machine can help to block outside traffic and hallway noises. A room air conditioner or fan can serve the same purpose. The temperature in the room should also be adjusted for sleeping comfort.

All **antioxidants** help to decrease the effects of jet lag. Extra doses of **vitamins** A, C, and E, as well as zinc and selenium, two days before and two days after a flight help to alleviate jet lag. Melatonin, a hormone which helps to regulate circadian rhythms, can also help to combat jet lag. Melatonin is available as an over-the-counter supplement in most health food stores and pharmacies, but no more than 3 milligrams (mg) should be used in a 24-hour period.

If weather prevents an individual from spending time in the sunlight, **light therapy** may be beneficial in decreasing jet lag symptoms. Light therapy, or **phototherapy**, uses a device called a light box, which contains a set of fluorescent or incandescent lights in front of a reflector. Typically, the patient sits for 30 minutes next to a 10,000-lux box (which is about 50 times as bright as an ordinary indoor light; lux is a measurement for illuminance). Light therapy is safe for most people, but those with eye diseases should consult a healthcare professional before undergoing the treatment.

Prognosis

Jet lag usually lasts 24–48 hours after travel has taken place. In that short time period, the body adjusts to the time change, and with enough rest and daytime exposure to sunlight, it returns to normal circadian rhythm.

According to the American Sleep Association, almost 93% of travelers will experience jet lag at some point in their travels. Generally, the human body will take one–half to one day to completely adapt to its new surroundings for every one time zone crossed. However, this relationship can vary drastically depending on individuals. For instance, frequent air travelers may have not have any symptoms of jet lag after years of flying, while people on their first flight may be already very nervous and anxious about their trip and may experience debilitating jet lag.

Prevention

One cannot prevent jet lag, but it can be minimized with the following recommendations. Eat a nutritious diet (foods do not have an effect on jet lag but eating healthy can assist the body to counter changes that it experiences while flying), and get plenty of rest and **exercise** before the flight. Exercising and sleeping are also two excellent ways to minimize jet lag. For any medical conditions that may cause problems during and after the flight, visit the doctor beforehand to prepare for such problems. It is always advisable to start preparing for one's new time zone before actually going. Adapt to the new time gradually over the days, or weeks, before the flight.

During the flight, do not drink alcoholic beverages and drinks with **caffeine**. Both beverages can increase the symptoms of jet lag. On the other hand, drink plenty of water to avoid **dehydration** that is present in the cabin of airplanes. For long journeys, move around inside the airplane on a regular basis. While in the seat, exercise the legs. For travelers able to take extra time in their flight, stay overnight in an in-between city.

Melatonin is still under consideration by the U.S. Food and Drug Administration (FDA) as to being effective or not in minimizing or even preventing jet lag. The nutritional supplement has been shown in some medical studies to be effective when 0.5 to 5 milligrams (mg) of melatonin are taken during the first few days of air travel. However, as of 2014, the FDA does not regulate it, and caution is advised for its use in countering jet lag. The FDA has also found that some melatonin products, especially those found on the Internet, have been found to contain contaminants that may cause unforeseen problems if taken by unsuspecting air travelers.

Jock itch

Definition

Also known as *Tinea cruris*, jock itch is a growth of fungus in the warm, moist area of the groin.

Description

Although there are many causes of jock itch, this term has become synonymous with *tinea cruris*, a common fungal infection that affects the groin and inner thighs of men and woman. *Tinea* is the name of the fungus; *cruris* comes from the Latin word for leg. Jock itch can develop when tight garments trap moisture and heat. This creates an environment in which fungi multiply and flourish. Athletes often get jock itch but non-athletic men who sweat a lot can also get it. Jock itch occurs more commonly in men, but can affect women as well. The jock itch fungus may cause a rash on the upper and inner thighs, the armpits, and the area just underneath the breasts. Many people with *tinea cruris* also have athlete's foot. Athlete's foot is called *tinea pedis*.

Causes and symptoms

The rash of jock itch starts in the groin fold usually on both sides. If the rash advances, it usually advances down the inner thigh. The advancing edge is redder and more raised than areas that have been infected longer. The advancing edge is usually scaly and very easily distinguished or well demarcated. The skin within the border turns a reddish-brown and loses much of its scale. Jock itch can spread to the pubic and genital regions and sometimes to the buttocks.

Jock itch caused by *T. rubrum* does not involve the scrotum or penis. If those areas are involved, the most likely agent is *Candida albicans*, the same type of yeast that causes vaginal yeast infections.

Diagnosis

Often a case of jock itch can be identified based on the characteristic description previously described. If assessed by a conventional doctor, the area of affected skin may be scraped onto a glass slide for definitive diagnosis under the microscope. In order to determine the exact type of fungus present, a small piece of affected skin maybe sent off to the lab for further study.

Treatment

Typical conventional treatment for jock itch involves the use of an anti-fungal cream, spray, or powder twice a day for about two weeks. Three commonly used, over-the-counter anti-fungals are *miconazole* (Micatin), *clotrimazole* (Lotrimin) and *tolnaftate* (Tinactin). While the tendency to discontinue treatment once **itching** disappears is common, it is important to use the anti-fungal for a full two-week course in order to prevent recurrence of the infection.

WWW.BOOKBAZ.IR

KEY TERMS

Fungus—A single-celled or multi-celled organism without chlorophyll that reproduces by spores and lives by absorbing nutrients from organic matter.

Scrotum—The external pouch of skin and muscle containing the testes (testicles).

Vaginal yeast infection—An overgrowth of fungus in the vaginal area.

Alternatives

Topical treatments include poultices of peppermint, oregano, or lavender. Tea tree oil, diluted with a carrier oil of almond oil, can be applied to the rash several times per day. Cedarwood and jasmine oils can relieve itching when applied in the same manner. Grapefruit seed extract can be taken as a strong solution of 15 drops in 1 oz of water.

Another alternative remedy for jock itch is to wash the groin area with the diluted juice of a freshly squeezed lemon, which can help dry up the rash. A hair dryer on the cool setting can also be used on the area after showering to dry it thoroughly. A warm bath relieves itching in many patients. The affected area should kept clean and dry, and loose-fitting, cotton underwear is recommended.

Prognosis

Treatment for jock itch is quick and usually effective, but the condition often comes back. With treatment, jock itch improves in two or three days and is completely gone in three or four weeks. The following people should be especially vigilant to prevent the problem from returning:

- Athletes
- People with fungal infections that affect other parts of the body (such as athlete's foot)
- People who wear tight clothing
- People with damaged or altered immune systems, including people with HIV or AIDS

Prevention

The best prevention of jock itch is cleanliness and sanitation. This includes keeping the groin area dry, wearing loose-fitting rather than tight clothing, wear boxer shorts rather than briefs, change sweat-covered clothes as soon as possible, showering immediately after working out or playing a sport and then applying talc, and washing workout clothes or sports uniforms after each use.

Joint aspiration *see* **Joint fluid analysis**

Joint biopsy

Definition

A joint or synovial membrane biopsy refers to a procedure where a sample of the joint lining or synovial membrane is taken.

Purpose

A joint biopsy is performed to determine why a joint is painful or swollen. It is usually reserved for more difficult cases where the diagnosis is not clear. The test can be used to diagnose bacterial or **fungal infections**, an abnormal buildup of iron, cancer, or other diseases.

Precautions

The procedure must be done under very sterile conditions to reduce the risk of infection.

KEY TERMS

Joint—The point where two bones meet.

Pathology—The branch of medicine that looks at abnormal changes in cells and tissues which signal disease.

Synovial membrane—Membrane lining a joint.

Trocar—A sharp pointed tube through which a needle can be inserted.

Description

The test is performed either in the doctor's office, clinic, or hospital by a surgeon. There are many different ways to perform this biopsy: through an incision in the joint; with a scope inserted in the joint; or, more typically, by the insertion of a sharp instrument through the skin. The procedure can be taken from any joint, but the most common joint requiring biopsy is the knee. A sharp instrument (trocar) is pushed into the joint space. A needle with an attached syringe is inserted into the joint to withdraw fluid for laboratory analysis. The surgeon may instill numbing medicine into the joint and along the needle track before the needle is withdrawn. The trocar and then the biopsy needle is inserted and specimens taken. After the specimen is taken, both the trocar and the biopsy needle are removed, a bandage is placed over the joint, and the samples are sent to pathology for analysis.

Preparation

Blood tests will be done to check that **blood clots** properly. A mild sedative may be given before the procedure. With the patient lying down, the skin over the joint is disinfected and a local anesthetic is injected into the skin and tissue just below the skin.

Aftercare

The joint will need rest for at least one day. Normal activity can resume if there is no increased **pain** or swelling.

Risks

There is a chance of joint swelling or tenderness. Rarely, bleeding and infection can occur in the joint, or the biopsy needle could break off or strike a nerve or blood vessel. The risk of infection is higher if the patient has an immune deficiency.

Joint endoscopy *see* **Arthroscopy**

Joint fluid analysis

Definition

Joint fluid analysis, also called synovial fluid analysis, or arthrocentesis, is a procedure used to assess joint-related abnormalities, such as in the knee or elbow.

Description

The test is also called arthrocentesis, joint tap, and closed joint aspiration. Normal synovial fluid is a clear or pale-yellow fluid found in small amounts in joints, bursae (fluid-filled sac found on points of friction, like joints), and tendon sheaths. The procedure is done by passing a needle into a joint space and sucking out (aspirating) synovial fluid for diagnostic analysis. When the sample is sent to the laboratory, the fluid is analyzed for color, clarity, quantity, and chemical composition. It is also examined microscopically to check for the presence of bacteria and other cells.

The procedure takes about 10 minutes. Prior to the procedure, any risks that are involved should be explained to the patient. No intravenous **pain** medications or sedatives are required, although the patient will be given a local anesthetic.

The patient is asked to lie on their back and remain relaxed. The local anesthetic, typically an injection of lidocaine, is then administered. The clinician is usually seated next to the patient. Then the clinician marks exactly where the needle is to enter. As the needle enters the joint, a "pop" may be felt or heard. This is normal. Correct placement of the needle in the joint space is normally painless. At this point, the clinician slowly drains some of the fluid into the syringe. The needle is then withdrawn and adhesive tape is placed over the needle site.

Purpose

The purpose of a joint fluid analysis is to identify the cause of swelling in the joints, to relieve pain and

WWW.BOOKBAZ.IR

KEY TERMS

Aspirate—The removal by suction of a fluid from a body cavity using a needle.

Bursae—A closed sac lined with a synovial membrane and filled with fluid, usually found in areas subject to friction, such as where a tendon passes over a bone.

Hematoma—A localized mass of blood that is confined within an organ or tissue.

Synovial fluid—A transparent lubricating fluid secreted in a sac to protect an area where a tendon passes over a bone.

distention from fluid accumulation in the joint, and to diagnose certain types of arthritis and inflammatory joint diseases. The test is also a method to determine whether an infection, either bacterial or fungal, exists within the joint.

Preparation

Glucose, or sugar, in the joint can be a signal of arthritis. If the clinician will be doing a glucose test, the patient will be asked to fast for six to 12 hours preceding the procedure. If not, there is no special preparation required for a joint fluid analysis.

Aftercare

Some post-procedural pain may be experienced. For this reason, the patient should arrange to be driven home by someone else. Aftercare of the joints will depend on the results of the analysis.

Results

The results of a normal joint fluid analysis include fluid of a clear or pale-yellow color and the absence of bacteria, fungus, and other cells, such as white blood cells.

The results of an abnormal joint fluid analysis include fluid that is turbid, or cloudy. Also, white blood cells and other blood cells may be found, from which the clinician can make a diagnosis and arrive at a treatment for the joint problem. An abnormal result can indicate an infection caused by a bacteria, or **tuberculosis**. Or, there might be inflammation that is caused by **gout**, **rheumatoid arthritis**, or **osteoarthritis**.

Risks

While joint fluid analysis is generally a safe procedure, especially when performed on a large, easily accessible joint, such as the knee, some risks are possible. Some of the complications to the procedure, although rare, include infection at the site of the needle stick, an accumulation of blood (hematoma) formation, local pain, injury to cartilage, tendon rupture, and nerve damage.

Joint fluid analysis should not be performed on any patient who is uncooperative, especially if the patient cannot or will not keep the joint immobile throughout the procedure. Patients with certain infections should be excluded from the procedure, particularly those who have a local infection along the proposed needle track. The joint space should be accessible. Therefore, a poorly accessible joint space, such as in hip aspiration in an obese patient, should not be subject to this procedure.

Juvenile arthritis

Definition

Juvenile arthritis (JA) is not a single disorder but a group of arthritides (plural of arthritis) that affect children and teenagers below the age of 16. JA has been known by various names since 1970, including juvenile **rheumatoid arthritis** (JRA), juvenile idiopathic arthritis (JIA), and juvenile chronic arthritis (JCA). All the conditions included under the general term of JA strike children under age 16, and all have immune-mediated joint inflammation as their major manifestation. The International League of Associations for Rheumatology (ILAR) has tried to bridge

these differences with a unifying set of criteria to define juvenile arthritis.

Demographics

According to the American College of Rheumatology (ACR), as of 2014 about one child in every 1,000 in the United States develops some form of JA. Doctors estimate that around 300,000 children in the United States have been diagnosed with JIA. Native Americans in both Canada and the United States have somewhat higher rates of JA than members of other racial and ethnic groups. Internationally, Norway and Australia have the highest rates of JA, while Africa and individuals of African ancestry appear to have lower than average rates. The reason for these differences is not yet known.

Description

The skeletal system of the body is made up of different types of the strong, fibrous tissue known as connective tissue. Bone, cartilage, ligaments, and tendons are all forms of connective tissue that have different compositions, and thus different characteristics.

The joints are structures that hold two or more bones together. Some joints (synovial joints) allow for movement between the bones being joined (called articulating bones). The simplest model of a synovial joint involves two bones, separated by a slight gap called the joint cavity. The ends of each articular bone are covered by a layer of cartilage. A tough tissue called the articular capsule surrounds both articular bones and the joint cavity. The articular capsule has two components: the fibrous membrane on the outside, and the synovial membrane (or synovium) on the inside. The fibrous membrane may include tough bands of fibrous tissue called ligaments, which are responsible for providing support to the joints. The synovial membrane has special cells and many capillaries (tiny blood vessels). This membrane produces a supply of synovial fluid that fills the joint cavity, lubricates it, and helps the articular bones move smoothly about the joint.

In JA, the synovial membrane becomes intensely inflamed. Usually thin and delicate, the synovium becomes thick and stiff, with numerous infoldings on its surface. The membrane becomes invaded by white blood cells, which produce a variety of destructive chemicals. The cartilage along the articular surfaces of the bones may be attacked and destroyed, and the bone, articular capsule, and ligaments may begin to be worn away. These processes severely interfere with movement in the joint.

JA specifically refers to chronic arthritic conditions that affect a child under the age of 16 years and last for a minimum of three to six months. JA is often characterized by a waxing and waning course, with flares separated by periods during which no symptoms are noted (remission). Some of the medical literature refers to JA as juvenile rheumatoid arthritis, although most types of JA differ significantly from the adult disease called rheumatoid arthritis, in terms of symptoms, progression, and prognosis.

Risk factors

The two major risk factors for JA are sex and race. Most forms of JA are more common in girls than in boys (the major exception being eye disorders), and more common in Caucasian and Native American children than in children of other races.

Causes and symptoms

Causes

A number of different causes have been sought to explain the onset of JA. There seems to be some genetic link, because the tendency to develop JA sometimes runs in a particular family, and because certain genetic markers are more frequently found in patients with JA and other related diseases. Genes that have been linked to increased susceptibility to JA include the *IL2RA/CD25* gene and the *VTCN1* gene.

Many researchers have looked for some infectious cause for JA, but no clear connection to a particular organism has ever been made. JA is considered by some to be an autoimmune disorder. **Autoimmune disorders** occur when the body's immune system mistakenly identifies the body's own tissue as foreign and goes about attacking those tissues as if trying to rid the body of an invader (such as a bacteria, virus, or fungi). While an autoimmune mechanism is strongly suspected, certain markers of such a mechanism (such as rheumatoid factor, often present in adults with such disorders) are rarely present in children with JA.

Symptoms

Joint symptoms of arthritis may include stiffness, **pain**, redness and warmth of the joint, and swelling. Bone in the area of an affected joint may grow too quickly, or too slowly, resulting in limbs that are of different lengths. When the child tries to avoid moving a painful joint, the muscle may begin to shorten from disuse. This is called a contracture.

WWW.BOOKBAZ.IR

Symptoms of JA depend on the particular subtype. According to criteria published by the American College of Rheumatology (ACR) in 1973 and modified in 1977, JRA is classified by the symptoms that appear within the first six months of the disorder:

- Pauciarticular JA: This is the most common and the least severe type of JA, affecting about 40–60% of all JA patients. This type affects fewer than four joints, usually the knee, ankle, wrist, and/or elbow. Other more general (systemic) symptoms are usually absent, and the child's growth usually remains normal. Very few children (less than 15%) with pauciarticular JA end up with deformed joints. Some children with this form of JA experience painless swelling of the joint. Some children with JA have a serious inflammation of structures within the eye, which if left undiagnosed and untreated could lead to blindness. This condition is known as uveitis, and affects about 20% of children diagnosed with JRA. While many children have cycles of flares and remissions, in some children the disease completely and permanently resolves within a few years of diagnosis.
- Polyarticular JA: About 40% of all cases of JA are of this type. More girls than boys are diagnosed with this form of JA. This type is most common in children up to age three or after the age of 10. Polyarticular JA affects five or more joints simultaneously. It usually affects the small joints of both hands and both feet, although other large joints may be affected as well. Some patients with arthritis in their knees experience a different rate of growth in each leg. Ultimately, one leg will grow longer than the other. About half of all patients with polyarticular JA have arthritis of the spine and/or hip. Some patients with polyarticular JA have other symptoms of a systemic illness, including anemia (low red blood cell count), decreased growth rate, low appetite, low-grade fever, and a slight rash. The disease is most severe in those children who are diagnosed in early adolescence. Some of these children test positive for a marker present in other autoimmune disorders, called rheumatoid factor (RF). RF is found in adults who have rheumatoid arthritis. Children who are positive for RF tend to have a more severe course, with a disabling form of arthritis that destroys and deforms the joints. This type of arthritis is thought to be the adult form of rheumatoid arthritis occurring at a very early age.
- Systemic-onset JA: Sometimes called Still disease (after a physician who originally described it), this is a type of JA that occurs in about 10–20% of all patients with JA. Boys and girls are equally affected, and diagnosis is usually made between the ages of 5–10 years. The initial symptoms are not usually related to the joints. Instead, these children have high fevers; a rash; decreased appetite and weight loss; severe joint and muscle pain; swollen lymph nodes, spleen, and liver; and serious anemia. Some children experience other complications, including inflammation of the sac containing the heart (pericarditis); inflammation of the tissue lining the chest cavity and lungs (pleuritis); and inflammation of the heart muscle (myocarditis). The eye inflammation often seen in pauciarticular JA is uncommon in systemic onset JA. Symptoms of actual arthritis begin later in the course of systemic onset JA, and they often involve the wrists and ankles. Many of these children continue to have periodic flares of fever and systemic symptoms throughout childhood. Some children will go on to develop a polyarticular type of JA.
- Enthesis-related arthritis (sometimes called spondyloarthropathy): This type of JA most commonly affects boys older than eight years of age. The arthritis occurs in the knees and ankles, moving over time to include the hips and lower spine. Inflammation of the eye may occur occasionally, but usually resolves without permanent damage.
- Psoriatic JA: This type of arthritis usually shows up in fewer than four joints, but spreads to include multiple joints (appearing similar to polyarticular JA). Hips, back, fingers, and toes are frequently affected. A skin condition called psoriasis accompanies this type of arthritis. Children often have pits or ridges in their fingernails. The arthritis usually progresses to become a serious, disabling problem.

There is some disagreement among specialists about the classification of JRA. Some prefer the EULAR classification, introduced in 1977, to the ACR system. More recently the International League of Associations for Rheumatology (ILAR) has identified a unifying set of criteria to define juvenile arthritis. Inconsistencies in naming the specific types of juvenile arthritis and their criteria for diagnosis continue to exist.

Diagnosis

The diagnosis of JA is not always obvious and may be delayed because some children do not complain of pain, and swelling of the joints may not be obvious.

Diagnosis of JA is usually made on the basis of the child's collection of symptoms together with elimination of other possible causes of the symptoms.

KEY TERMS

Articular bones—Two or more bones connected with each other via a joint.

Biologics—A class of drugs produced by means of biological processes involving recombinant DNA technology.

Congenital—Present at birth.

Contracture—Shortening of a muscle or joint due to a disease condition or injury.

Flare—A recurrence or worsening of the symptoms of JA.

Idiopathic—Of unknown cause or spontaneous origin. JRA is sometimes called juvenile idiopathic arthritis or JIA because its causes are still not fully known.

Joint—A structure that holds two or more bones together.

Rheumatology—The branch of medicine that specializes in the diagnosis and treatment of disorders affecting the muscles and joints.

Synovial joint—A particular type of joint that allows for movement in the articular bones.

Synovial membrane—The membrane that lines the inside of the articular capsule of a joint and produces a lubricating fluid called synovial fluid.

Uveitis—Inflammation of the pigmented vascular covering of the eye, which includes the choroid, iris, and ciliary body. Uveitis is a common complication of JRA.

Disorders to be ruled out include lupus, **Lyme disease**, certain bone disorders, infections, and childhood cancer. The diagnosis will usually involve a referral from the child's pediatrician to a rheumatologist, a physician specializing in disorders of the muscles and joints).

Examination

Symptoms of JA that the doctor can observe or measure during an office physical include:

- limping
- fever
- difficulty in moving or using an arm or leg
- swollen joint(s)
- skin rash on the chest, arms, or legs that comes and goes with fever
- swollen lymph nodes
- enlarged liver and spleen
- red eyes
- pain when a bright light is shone in the eye.

Tests

There is no blood test as of 2014 that can be used to diagnose JA, and other laboratory tests often show normal results. A blood test may be useful in ruling out certain infections as a cause of the child's symptoms. Some nonspecific indicators of inflammation may be elevated, including **white blood cell count**, **erythrocyte sedimentation rate**, and a marker called **C-reactive protein**. As with any chronic disease, anemia may be present. Children with an extraordinarily early onset of the adult type of rheumatoid arthritis will have a positive test for rheumatoid factor.

Imaging studies (most often x rays) may be taken to rule out broken or fractured bones, congenital defects in the joints, tumors, or some types of **infectious disease**. X-ray studies may also be done to monitor the development of the child's bones. **Magnetic resonance imaging** (MRI) and **ultrasound** are used increasingly to detect damage caused by JA in order to prevent further damage to the child's joints.

Procedures

In some cases the doctor may tap a swollen joint by inserting a small hollow needle into the joint to withdraw some of the fluid. This fluid can be analyzed to help determine the cause of the arthritis. In addition, withdrawing fluid may ease the discomfort in the joint.

Treatment

Mainstream treatment of JA involves the use of appropriate medications together with physical and **occupational therapy** as needed. Some children with JA may eventually need surgery, including joint replacement, and others may require psychological counseling to cope with depression or anger related to their symptoms. The goal of therapy is to control symptoms, maintain functioning of the child's joints, and prevent damage to the joints.

WWW.BOOKBAZ.IR

Drugs

Treating JA involves efforts to decrease the amount of inflammation in order to preserve movement. Medications that can be used for this include such nonsteroidal anti-inflammatory agents (NSAIDs) as ibuprofen (Motrin, Ibuprin), naproxen (Aleve, Naprelan, Naprosyn), diclofenac (Voltaren, Cataflam), and Tolmetin (Tolectin). Oral steroid medications are effective but have many serious side effects with long-term use. Injections of **steroids** into an affected joint can be helpful. Steroid eye drops are used to treat eye inflammation. Occasionally, splints are used to rest painful joints and to try to prevent or improve deformities.

Children who do not respond to treatment with NSAIDs may be given disease-modifying **antirheumatic drugs** or DMARDs. DMARDs include such medications as hydroxychloroquine (Plaquenil), sulfasalazine (Azulfidine), and methotrexate (Rheumatrex). More recent agents used to treat JA include biologics, which are drugs produced using recombinant DNA technology. Biologics used to treat JA include etanercept (Embrel), infliximab (Remicade), adalimumab (Humira), and abatacept (Orencia). Biologics work by blocking high levels of proteins that cause inflammation in the body.

Alternatives

Juice therapy has been suggested as an alternative treatment for arthritis. It works to detoxify the body, helping to reduce JA symptoms. Some recommended fruits and vegetables to include in the juice are carrots, celery, cabbage, potatoes, cherries, lemons, beets, cucumbers, radishes, and garlic. Tomatoes and other vegetables in the nightshade family (potatoes, eggplant, red and green peppers) are discouraged.

As an adjunct therapy, **aromatherapy** preparations use cypress, fennel, and lemon. Massage oils include rosemary, benzoin, chamomile, camphor, juniper, and lavender. Other types of therapy that have been used include **acupuncture**, **acupressure**, and bodywork.

Nutritional supplements that may be beneficial include large amounts of **antioxidants** (**vitamins** C, A, E, zinc, selenium, and flavenoids), as well as B vitamins and a full complement of **minerals** (including boron, copper, manganese). Other nutrients that assist in detoxifying the body, including methionine, cysteine, and other amino acids, may also be helpful. A number of autoimmune disorders, including JA, seem to have a relationship to **food allergies**. Identification and elimination of reactive foods may result in a decrease in JA symptoms. Constitutional homeopathy can work to quiet the symptoms of JA and bring about balance to the whole person. None of these alternative treatments, however, have been proven effective in clinical trials that meet the standards of conventional Western medicine.

Prognosis

The prognosis for pauciarticular JA is quite good, as is the prognosis for spondyloarthropathy. Polyarticular JA carries a somewhat worse prognosis; children who have many joints involved, or who have a positive rheumatoid factor are more likely to have chronic pain, disability, and problems with school attendance. Systemic onset JA has a variable prognosis, depending on the organ systems affected, and the progression to polyarticular JA. JRA is rarely life-threatening; however, about 1–5% of all JA patients die of such complications as infection, inflammation of the heart, or **kidney disease**. In addition, depression and other psychological problems are common in children with JA, particularly when they enter their teen years. Many children benefit from support groups and special summer camp programs for children with JA.

Prevention

Because so little is known about the causes of JA, there are no recommendations for preventing its development.

K

K-2 synthetic marajuana (Spice)

Definition

Spice or K2 is a commercially -available blend of herbs and synthetic cannabinoid, or synthetic **marijuana**. Spice can be smoked, like marijuana, or mixed into an herbal drink to achieve psychoactive effects similar to marijuana, including relaxation, a blissful high, and **hallucinations**.

Description

Since the 2000s, synthetic cannabinoids have been mixed with a variety of potentially psychoactive herbs and sold under a variety of guises (including incense and plant food). Different brands of Spice are labeled to contain some variety of psychoactive herbs including (but not limited to): beach bean, white or blue water lily, dwarf skullcap, Indian warrior, lion's ear/tail, wild dagga, machonha brava, blue or sacred lotus, honeyweed, Siberian motherwart, marshmallow, dog rose, and rosehip.

Spice is known by many names and sold under many brands including (but not limited to): K2, fake weed, Yucatan Fire, Skunk, and Moon Rocks.

The human body has cannabinoid receptors, two of which were discovered in the 1980s and are associated with the central nervous and immune systems. When the tetrahydrocannabinol (THC) in marijuana (cannabis) connects with the receptors in the central nervous system, it creates psychoactive effects. When Spice or synthetic cannabinoids connect with the same receptors, the effects are the same and are often stronger than the effects of natural marijuana. Many users of Spice—especially those that use the drug for an extended period of time—report additional effects including aggression, **anxiety**, **paranoia**, and hallucinations, heart **palpitations**, **vomiting**, agitation, confusion, myocardial ischemia (reduced blood supply to the heart), and even heart attacks. Regular uses may also experience symptoms of withdrawal similar to those of other drug addicts.

Deaths have been attributed to Spice for a variety of reasons—including **suicide**, overdose, and homicide. Patients under the influence of Spice have been known to attack medical personnel. An individual's response to Spice seems to be unpredictable and, as of 2014, there have not been scientific studies to determine exactly how Spice works on the brain or the full range of its effects. The psychoactive effects of Spice have lead to a variety of bizarre incidents that have made national news. In a case in Detroit, a 19 year-old man—a long-time user of K2—and his 20 year-old friend beat the man's father to death with a baseball bat and nearly killed the man's mother and brother in the same manner. In another bizarre case in Texas, a 22 year-old man—who was under the influence of Spice—crawled on his hands and knees, chasing a neighbor and barking like a dog. Shortly afterward, the same man captured a neighbor's dog, choked it, and then began to eat it.

Origins

Synthetic cannabinoids were originally developed from the 1960s–1990s in laboratories for a variety of pharmaceutical purposes. Since Spice is sold under so many names and for so many purposes, drug enforcement task forces in the United States and Europe have had difficulty tracking the origins of Spice and regulating its sale. The European Monitoring Centre for Drugs and Drug **Addiction** estimates that Spice or similar products first appeared on the market around 2004.

Demographics

According to the *Clinical Psychiatry News*'s interview with the American Association of Poison Control Centers (AAPCC), in 2011, calls related to synthetic marijuana were up to 6,959 from 2,906 in 2010.

According to a 2011 study by the University in Michigan and the National Institute on Drug Abuse (NIDA)—the first to question minors about their use of synthetic drugs)—roughly one in nine high school seniors reported having used Spice in 2011, which makes Spice the second most popular illicit drug (after marijuana) for this age group.

Effects on Public Health

Since Spice is a relatively new **public health** concern—the full range of its effects have yet to be realized. As of 2014, there are no existing scientific data to help the medical, law enforcement, and policy-making communities properly combat the threat. Until scientific tests are available, the human health and toxicity consequences of Spice remain unknown, though NIDA suspects harmful heavy metal residues may be present in Spice compounds. U.S. Customs and Border Protection believes that many of the Spice products available in the United States originate from overseas locales—increasing the potential for variation and inclusion of toxic substances or traces.

Treatment and solutions

The Synthetic Drug Control Act (H.R. 1254)—which seeks to add a variety of synthetic cannabinoids and synthetic hallucinogenics to the drugs on the Controlled Substance Act—was passed by the U.S. House of Representatives in 2011, and signed into law in 2012.

As of 2014, at least 45 states and Puerto Rico had enacted a ban on synthetic marijuana. The efficacy of these bans, however, remains unclear. The many product names, ingredients, and advertised uses for Spice make it a difficult substance to regulate effectively.

Spice falls into the category of "designer drug," and as such, its molecular structure frequently changes, leading to increased difficulty in detection. In addition to the multiple forms of synthetic cannabinoids, there are numerous psychoactive herbs with which the cannabinoids can be mixed. As a result, there are numerous formulations for the drug. This complexity makes it even harder to develop comprehensive tests to screen for Spice.

The tests currently available to screen for drugs are "structure-based," meaning that they detect certain structural elements of a known substance. The many potential and varying components of Spice make these types of tests ineffective. NIDA is offering funding to researchers who may be able to develop "biofluid" tests, which can detect ranges of a substances in bodily fluids for a predetermined amount of time.

KEY TERMS

Psychoactive drug—A drug that affects the central nervous system by crossing the blood-brain barrier. These drugs cause alterations in the brain's ability to function normally.

Cannabinoid—Any one of a class of compounds that stimulate the cannabinoid receptor sites in the human body. In humans, cannabinoid receptors primarily affect the nervous system—including the brain, spinal cord, and peripheral nerves—and the immune system—which helps the body fight disease and infection. Cannabinoids are separated into three classifications: endocannabinoids (which are produced naturally within the body); phytocannabinoids (which are found in plants) including tetrahydrocannabinol (THC), the psychoactive component of cannabis; and synthetic cannabinoids (which are manufactured in a laboratory).

Designer drugs—a class of substances that are specifically created to avoid traditional means of detection, including drug laws and testing. Designer drugs often consist of multiple variations of an original compound or they are created to mimic the effects of other popular illicit drugs.

As of 2014, Redwood Toxicology Laboratory (RTL) has developed an oral fluid (saliva) test for synthetic cannabis that is able to detect seven other synthetic cannabinoids. As RTL refines its processes and increases the number of compounds the tet is able to detect, the number of positive results for a specific compound fluctuate. RTL reports that after adding a particular synthetic cannabinoid compound to their detectable list, rates of positivity for that compound decline. From such results, RTL is able to document changes in manufacturer's ingredients.

Drugfree.org offers an awareness kit that features a slide presentation, podcast, and video about synthetic drugs, including Spice. The kit also includes a printable guide to synthetic drugs and street names.

Kaposi's sarcoma

Definition

Kaposi's sarcoma (KS) is a form of cancer that is manifested by lesions on the skin and can also progress to involve internal organs. It most often is found in patients with acquired **immunodeficiency** syndrome (**AIDS**) and can be fatal.

Demographics

The incidence of KS was very rare in the United States before the AIDS epidemic with only 19 cases reported in men between the ages of 20 and 54 years in the years 1975 to 1980. In 1981, an aggressive form of KS began to appear in homosexual men. At that time, almost half of homosexual men diagnosed with AIDS also developed KS. Incidence of KS peaked in 1989 and has decreased significantly since that time as a result of safer sexual practices and the introduction of highly active antiretroviral therapy (HAART). Among transplant patients, the incidence rate is about one in every 200 patients. At this time about 2500 new cases of KS are diagnosed each year in the United States, although there may be some underreporting of cases in the AIDS population.

Internationally, the incidence of KS remains very high in Africa. The highest rates of classic KS are found in Sicily and in Sardinia. These cases are, in general, unrelated to AIDS.

This HIV-positive patient is afflicted with Kaposi's sarcoma inside the mouth. *(Custom Medical Stock Photo, Inc.)*

Description

Kaposi's sarcoma (KS) was once a very rare form of cancer, primarily affecting elderly men of Mediterranean and eastern European background, until the 1980s, when it began to appear among AIDS patients. It manifests in four distinct forms. The first form, called classic or sporadic KS, was described by the Austrian dermatologist Moritz Kaposi more than a century ago. Classic KS usually affects older men of Mediterranean or eastern European ancestry by producing tumors on the lower legs. Though at times painful and disfiguring, the tumors generally are not life-threatening. The second form of the disease,

Kaposi's sarcoma usually appears on the lower extremities, as evidenced on this patient's hip. *(Custom Medical Stock Photo, Inc.)*

African endemic KS, affects boys and men primarily. It can appear as classic KS, or in a more deadly form that quickly spreads to tissues below the skin, the bones, and lymph system, leading to death within a few years of diagnosis. Another form of KS, immunocompromised KS, is observed in kidney and liver transplant patients who take immunosuppressive drugs to prevent rejection of their organ transplant. Immunocompromised KS usually reverses after the immunosuppressive drug is stopped. The fourth form of KS, epidemic AIDS-related KS, emerged as one of the first illnesses observed among those with AIDS. Unlike classic KS, AIDS-related KS tumors occur in advanced HIV infection and generally appear on the upper body, including the head, neck, and back. Tumors also can appear on the soft palate and gum areas of the mouth. In more advanced cases, they can be found in the stomach and intestines, the lymph nodes, and the lungs.

Causes and symptoms

Classic KS, which typically results in a disease course which is long and generally indolent, is thought to be caused by immune system dysregulation (a combination of factors which lead to immune suppression and immune activation) although the exact cause has not yet been identified. Currently, it is thought that this type of KS may be caused by suppression of the immune system as the individual ages, as a result of the genetic makeup of the patient, as a result of diagnosis with another type of cancer in the same individual and possibly results from concurrent malarial infection in some people.

The cause of immunocompromised KS appears to be directly related to treatment with immunosuppressive drugs following organ transplant or in patients receiving immunosuppressive therapies. These patients' risk for developing KS is increased by 100 times. Most patients develop this type of KS within 15–30 months following transplant. As stated earlier, once the patient stops taking the immunosuppressive drugs, the KS may regress. A newer antirejection drug, sirolimus (Rapamune), has been shown to have a dual effect which is advantageous to transplant patients who have been diagnosed with KS. Sirolimus appears to have an immunosuppressive effect as well as an antitumor (anti-KS) effect. A small group of kidney transplant patients who were diagnosed with KS post-transplant were switched from the immunosuppressive drug cyclosporine to sirolimus. All of the patients in this study experienced regression of their KS; all cutaneous KS lesions in all of the patients disappeared. In addition, none of these patients experienced rejection.

The cause of African KS is also linked to immune dysregulation. This type of KS occurs primarily in men but also occurs in African women and children, often in individuals who are not HIV positive. The course of this type of KS can be aggressive or indolent. African KS involves the lymph nodes more often than the classic form of KS. In African children who are not HIV positive and who are diagnosed with African KS, lymph node involvement may also be accompanied by visceral KS. This KS disease pattern results in an extremely poor prognosis; virtually 100% of the children with this disease profile are dead within three years.

Epidemic AIDS-related KS is the most aggressive form of KS and is associated with patients with advanced HIV infection who are severely immunocompromised. It appears that infection with human herpes virus 8 (HHV-8) must be present for this type of KS to develop. HHV-8 is transmitted via saliva. It is not yet known whether the virus can be spread via

WWW.BOOKBAZ.IR

MORIZ KAPOSI (1837–1902)

Moriz Kohn Kaposi was born in 1837 to very poor Hungarian parents. He studied dermatology under Ferdinand von Hebra at the University of Vienna, earning his medical degree in 1861. Kaposi took a position in Hebra's clinic and ultimately became a lecturer where he was responsible for educating numerous dermatologists. Kaposi and Hebra coauthored *The Handbook of Diseases of the Skin* which had great success. Kaposi married Hebra's daughter and the couple had one son, Hermann (1872). When Hebra died, Kaposi filled the vacant spot as director of the skin clinic and as Vienna's most renowned dermatologist.

Between 1872 and 1887, Kaposi discovered nine skin diseases that had not been previously documented. His discovery of a malignant disease that strikes the lymph nodes and skin (Kaposi's sarcoma 1872) has been documented as the most noteworthy. This disease was seen relatively rarely in the United States until the 1980s when it was tied to AIDS. This sarcoma has been the most common tumor found in AIDS patients. In 1872, Kaposi also studied cases of lupus erythematosus, which had no previous documentation. Kaposi was a prolific writer who published *Pathology and Treatment of Diseases of the Skin* in addition to numerous other publications, which he completed individually and with other authors. Kaposi died in 1902.

blood-borne transmission. KS may be caused by HHV-8 and activation of other immune system factors including oncostatin M, IL-1, IL-6, fibroblast growth factor, **tumor necrosis factor**, and the HIV-tat protein, which act as co-stimulants, as well as other abnormal cytokines. A patient infected with HHV-8 who is co-infected with HIV, appears to be much more susceptible to an aggressive KS disease course. Patients who are co-infected with HHV-8 and HIV are 500 to 10,000 times more likely to develop KS.

Therefore, a very complex combination of factors appears to contribute to the development of all four variants of KS. This combination of factors is likely to include environmental factors, immune system factors, infection with human herpesvirus 8 (HHV-8) and in some individuals, co-infection with HIV.

Symptoms of Kaposi's sarcoma vary depending on the extent of the disease. KS produces pink, purple, or brown tumors on the skin, mucous membranes, or internal organs. Other symptoms which may be present, depending on the extent of the disease, include tumor–associated **lymphedema**, **pain** associated with walking if lesions are present on the feet, a variety of gastrointestinal symptoms if the lesions are present in the gastrointestinal tract, as well as **cough**, difficulty breathing, coughing up blood, and chest pain if pulmonary involvement is present.

Diagnosis

Many physicians diagnose KS based on the appearance of the skin tumors and the patient's medical history. Unexplained cough or chest pain, as well as unexplained stomach or intestinal pain or bleeding, can suggest that the disease has moved beyond the skin. The most certain diagnosis can be achieved by taking a biopsy sample of a suspected KS lesion and examining it under high-power magnification. For suspected involvement of internal organs, physicians use a bronchoscope to examine the lungs or an endoscope to view the stomach and intestinal tract. Tests such as the CD4 lymphocyte count and plasma HIV viral-load studies may be conducted on patients diagnosed with HIV.

Treatment

Treatment goals for KS are simple: to reduce the severity of symptoms, shrink tumors, and prevent disease progression. The advent of HAART has resulted in marked advancements in the treatment of KS and is generally the first therapy initiated. Most patients respond very well to HAART although response is dependent on stage of disease. Patients diagnosed with KS that has not affected the visceral organs may receive HAART as the sole treatment modality.

Patients whose disease has spread to the visceral organs and who are considered to be poor risk KS patients may be treated with a variety of modalities including **chemotherapy** which is used with palliative intent. Chemotherapy drugs approved by the FDA to treat AIDS-related KS include liposomal doxorubicin (Doxil), used in patients who have been previously treated; liposomal daunorubicin (DaunoXome), which is approved as a first-line treatment option; and paclitaxel (Taxol), also approved for patients who have been previously treated. These drugs have resulted in high response rates often with less toxicity as compared to other drugs.

In addition, **radiation therapy** may be used and is often very effective in treating lesions that are considered to be advanced and symptomatic. Surgery may be

KEY TERMS

African endemic Kaposi's sarcoma—A form of KS that affects men and boys and that can appear like classic KS or in a more lethal form.

AIDS–related Kaposi's sarcoma—A form of KS that emerged as one of the first illnesses associated with AIDS patients. Tumors usually appear on the upper body, the soft palate and gum areas, and, as the disease advances, in the lymph nodes, stomach, intestines, and lungs.

Apoptosis—Cell death.

Classic Kaposi's sarcoma—A form of KS that usually affects older men of Mediterranean or eastern European backgrounds and produces tumors on the lower legs.

Cytokines—Regulatory proteins that are produced by the immune system.

Human herpesvirus 8—Also called Kaposi's sarcoma–associated herpesvirus (KSHV), this virus is thought to be a cause for KS.

Iatrogenic Kaposi's sarcoma—A form of KS that develops in transplant patients who take immunosuppressive drugs to prevent rejection of their organ transplant.

MCH–1—Major histocompatibility complex proteins that protect cells from invasion.

an option to remove small superficial KS lesions. Some KS lesions may be treated with chemotherapy such as vincristine or vinblastine injected directly into the lesion (intralesional therapy) although the lesions are likely to recur in other areas. Systemic infusion of chemotherapy drugs may be more effective. Other treatment options which may be employed include **cryotherapy** with liquid nitrogen applied topically to treat small facial lesions, laser photocoagulation to shrink small lesions, and application of topical retinoids such as alitretinoin (Panretin) gel to lesions.

Interferon-alfa, interferon combined with chemotherapy, interleukin-12, and chemotherapy using a variety of agents have been used as palliative agents to treat KS that is symptomatic or life-threatening. Treatment options being explored in clinical trials include therapy with thalidomide and other antiangiogenesis agents. Other trials are focused on investigating whether antiviral therapy utilizing drugs such as foscarnet and ganciclovir may be effective because of the link between human herpesvirus and KS.

Prognosis

The prognosis for patients with classic KS is good. Tumors can frequently be controlled and patients frequently die of other causes before any serious spread. African endemic KS can progress rapidly and lead to premature death, despite treatment. In AIDS-related KS, milder cases can frequently be controlled; the prognosis for more advanced and rapidly progressing cases is less certain and dependent on the patient's overall medical condition. There are indications that KS can be stabilized or reversed in patients whose level of HIV in the blood is reduced to undetectable levels via combined antiretroviral therapy.

Prevention

Safer sex practices may help to prevent AIDS-related KS by decreasing the risk of transmission of HHV-8 through sexual means. Treatment with antiretrovirals may help to preserve the function of the immune system in HIV patients and delay the appearance and progression of KS lesions. In fact, since the introduction of HAART in those infected with HIV, KS has decreased substantially. However, it still remains the most common cancer among those infected with HIV.

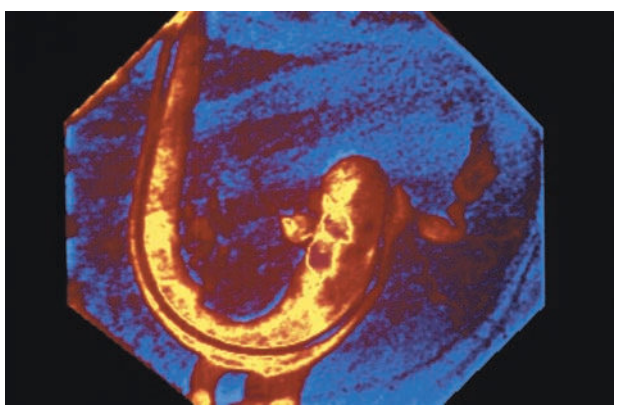
Kawasaki syndrome

Definition

Kawasaki syndrome is a potentially fatal inflammatory disease that affects several organ systems in the body, including the heart, circulatory system, mucous membranes, skin, and immune system. It occurs primarily in infants and children but has also been identified in adults as old as 34 years. Its cause is unknown.

Description

Kawasaki syndrome, also called mucocutaneous lymph node syndrome (MLNS), is an inflammatory disorder with potentially fatal complications affecting the heart and its larger arteries. Nearly twice as many males are affected as females. Although persons of Asian descent are affected more frequently than either black or white individuals, there does not appear to be a distinctive geographic pattern of occurrence. Eighty percent of cases involve children under the age of four. Although the disease usually appears in individuals, it sometimes affects several members of the same family and occasionally occurs in small epidemics.



An angiogram showing abnormal coronary arteries in a child suffering from Kawasaki's disease. The coronary arteries are abnormal and weakened in that they bulge into balloon shapes, or aneurysms, along their lengths. *(Mehau Kulyk/SPL/Photo Researchers, Inc.)*

Causes and symptoms

The specific cause of Kawasaki syndrome is unknown, although the disease resembles infectious illnesses in many ways. It has been suggested that Kawasaki syndrome represents an allergic reaction or other unusual response to certain types of infections. Some researchers think that the syndrome may be caused by the interaction of an immune cell, called the T cell, with certain poisons (toxins) secreted by bacteria.

Kawasaki syndrome has an abrupt onset, with **fever** as high as 104°F (40°C) and a rash that spreads over the patient's chest and genital area. The fever is followed by a characteristic peeling of the skin beginning at the fingertips and toenails. In addition to the body rash, the patient's lips become very red, with the tongue developing a "strawberry" appearance. The palms, soles, and mucous membranes that line the eyelids and cover the exposed portion of the eyeball (conjuntivae) become purplish-red and swollen. The lymph nodes in the patient's neck may also become swollen. These symptoms may last from two weeks to three months, with relapses in some patients.

In addition to the major symptoms, about 30% of patients develop joint pains or arthritis, usually in the large joints of the body. Others develop **pneumonia**, **diarrhea**, dry or cracked lips, **jaundice**, or an inflammation of the membranes covering the brain and spinal cord (**meningitis**). A few patients develop symptoms of inflammation in the liver (hepatitis), gallbladder, lungs, or tonsils.

About 20% of patients with Kawasaki syndrome develop complications of the cardiovascular system. These complications include inflammation of the heart tissue (**myocarditis**), disturbances in heartbeat rhythm (**arrhythmias**), and areas of blood vessel dilation (aneurysms) in the coronary arteries. Other patients may develop inflammation of an artery (arteritis) in their arms or legs. Complications of the heart or arteries begin to develop around the tenth day after the illness begins, when the fever and rash begin to subside. A few patients may develop **gangrene**, or the death of soft tissue, in their hands and feet. The specific causes of these complications are not yet known.

Diagnosis

Because Kawasaki syndrome is primarily a disease of infants and young children, the disease is most likely to be diagnosed by a pediatrician. The physician will first consider the possible involvement of other

diseases that cause fever and skin **rashes**, including **scarlet fever**, **measles**, **Rocky Mountain spotted fever**, **toxoplasmosis** (a disease carried by cats), juvenile **rheumatoid arthritis**, and a blistering and inflammation of the skin caused by reactions to certain medications (Stevens-Johnson syndrome).

Once other diseases have been ruled out, the patient's symptoms will be compared with a set of diagnostic criteria. The patient must have a fever lasting five days or longer that does not respond to **antibiotics**, together with four of the following five symptoms:

- Inflammation of the conjunctivae of both eyes with no discharge
- At least one of the following changes in the mucous membranes of the mouth and throat: "strawberry" tongue; cracked lips; or swollen throat tissues
- At least one of the following changes in the hands or feet: swelling caused by excess fluid in the tissues; peeling of the skin; or abnormal redness of the skin
- A skin eruption or rash associated with fever (exanthem) on the patient's trunk
- Swelling of the lymph nodes in the neck to a size greater than 1.5 cm.

Since the cause of Kawasaki syndrome is unknown, there are no laboratory tests that can confirm the diagnosis. The following test results, however, are associated with the disease:

- Blood tests show a high white blood cell count, high platelet count, a high level of protein in the blood serum, and mild anemia
- Chest x ray may show enlargement of the heart (cardiomegaly)
- Urine may show the presence of pus or an abnormally high level of protein
- An electrocardiogram may show changes in the heartbeat rhythm

In addition to these tests, it is important to take a series of echocardiograms during the course of the illness because 20% of Kawasaki patients will develop coronary aneurysms or arteritis that will not appear during the first examination.

Treatment

Kawasaki syndrome is usually treated with a combination of **aspirin**, to control the patient's fever and skin inflammation, and high doses of intravenous immune globulin to reduce the possibility of coronary artery complications. Some patients with heart complications may be treated with drugs that reduce blood clotting or may receive corrective surgery.

KEY TERMS

Aneurysm—Dilation of an artery caused by thinning and weakening of the vessel wall.

Arrythmia—Abnormal heart rhythm.

Arteritis—Inflammation of an artery.

Cardiomegaly—An enlarged heart.

Conjunctivae—The mucous membranes that cover the exposed area of the eyeball and line the inner surface of the eyelids.

Exanthem—A skin eruption associated with a disease, usually one accompanied by fever as in Kawasaki syndrome.

Gangrene—The death of soft tissue in a part of the body, usually caused by obstructed circulation.

Hepatitis—Inflammation of the liver.

Meningitis—Inflammation of the membranes, called the meninges, covering the brain and spinal cord.

Mucocutaneous lymph node syndrome (MLNS)—Mucocutaneous lymph node syndrome, another name for Kawasaki syndrome. The name comes from the key symptoms of the disease, which involve the mucous membranes of the mouth and throat, the skin, and the lymph nodes.

Myocarditis—Inflammation of the heart muscle.

Stevens-Johnson syndrome—A severe inflammatory skin eruption that occurs as a result of an allergic reaction or respiratory infection.

T cell—A type of white blood cell that develops in the thymus gland and helps to regulate the immune system's response to infections or malignancy.

Follow-up care includes two to three months of monitoring with chest x rays, **electrocardiography**, and **echocardiography**. Treatment with aspirin is often continued for several months.

Prognosis

Most patients with Kawasaki syndrome will recover completely, but about 1–2% will die as a result of **blood clots** forming in the coronary arteries or as a result of a **heart attack**. Deaths are sudden and unpredictable. Almost 95% of fatalities occur within six months of infection, but some have been reported as long as 10 years afterward. Long-term follow-up of patients with aneurysms indicates that about half show some healing of the aneurysm. The remaining half has a high risk of heart complications in later life.

Keloids

Definition

Keloids are excessive (overgrowths) of fibrous tissue or **scars** that can occur after an injury to the skin has healed (such as a burn), at the site of intentional alterations of the skin (such as an ear piercing), or as the result from medical procedures or illnesses (such as a **vaccination** or the **chickenpox**). Sometimes, they develop without any apparent cause. These heavy, sometimes irregular, and often very noticeable scars are also called cheloid, keloid, or hypertrophic scars. In individuals prone to keloids, even minor traumas to the skin, such as ear piercing, can cause keloids. The word "keloid" itself comes from the Greek word for a crab's claw; it was first used by a French physician to describe the way that keloids grow sideways into normal skin. The term keloidosis is intended to describe the situation when many keloids have occurred in one individual.

Demographics

Keloids are somewhat common in women and young people under the age of 30 years. They are also commonly found in families, with the malady inherited from one generation to the next. They occur most frequently in individuals of African–American descent and in those with darker skin. They are more common in Polynesians and Chinese than in people from India or Malaysia. Caucasians are the least frequently affected by keloids. Other risk factors include a family history of keloids, surgery, **acne**, **burns**, ear piercing, vaccinations, or insect bites. Spontaneous keloids have been reported occasionally in siblings. Keloids are infrequently found among the elderly.

Although the association of keloids with darker skin pigmentation suggests a genetic linkage of some sort, no specific genes have been identified in connection with keloids as 2014.

Description

Keloids usually start out as a small bump or raised spot on the skin. The size of the bump gradually becomes larger over time, and eventually becomes a mature keloid. Keloids can occur anywhere on the body, but they are most common on the earlobes, upper back, shoulders, and chest. The pattern of distribution of keloids differs according to race, with facial keloids more common in Caucasians and relatively uncommon in Asians. African Americans are more likely to develop keloids on the legs or feet than among either Asians or Caucasians. In general, keloids consist of hard, raised scars that may be slightly pink or whitish. They may itch and be painful, and some keloids can grow to be quite large.

Causes and symptoms

Although the cause of keloids is unknown, it is thought that they are due to the body's failure to turn off the healing process needed to repair skin. When this occurs, extra collagen forms at the site of the scar, and keeps forming because healing does not shut down, resulting in keloid formation. Scientists working on genomics, or the determination of the entire DNA (deoxyribonucleic acid) sequence of organisms, may one day learn the cause(s) of keloids.

Initially, keloids begin as a small lump where the skin has been injured. This lump grows and can eventually become very large and cosmetically unacceptable. Keloids often result from the following conditions:

- Chickenpox
- Acne
- Burns
- Piercings
- Scratches
- Cuts from surgeries
- Wounds
- Vaccinations

The symptoms associated with keloids include lesions that are:

- Flesh-colored, red, or pink
- Nodular or ridged
- At the site of an injury or wound
- Itchy while growing

Diagnosis

A dermatologist can usually make the diagnosis of a keloid based on looking at the scar or the appearance of the skin. In some cases, however, a biopsy may be

necessary to rule out other types of **skin lesions**, such as tumors.

Treatment

Most keloids do not need treatment. When they do, several options are available. The treatment of choice for keloids is usually an injection of corticosteroid drugs such as cortisone directly into the lesion. These injections cause the keloid to become atrophic, or thinner, and are repeated every three to four weeks until the keloid has been resolved to the individual's satisfaction. Other therapies include laser treatment or **radiation therapy**, and topical treatments are undergoing study.

Surgery is often used in combination with corticosteroid injections. The injections are given for several weeks, and then the keloid is surgically removed. The injections are then continued for several weeks. Surgical removal of the keloid may also be used in conjunction with radiation therapy, which delivers small amounts of radiation to the affected area.

Another surgical option is cryosurgery, in which liquid nitrogen is used to freeze the tissues in the keloid. The treatment may need to be repeated to remove as much of the keloid as possible; however, cryosurgery prevents keloids from recurring in about 70% of patients.

Newer approaches include silastic gel sheeting, which makes use of pressure to flatten the keloid. The patient is advised to apply a silastic gel each night for several months. The gel is then kept securely in place with tape, cloth, or a bandage. The dressing is changed daily for seven to 10 days for minor cases, and for as long as 12 months in very serious cases.

Finally, researchers are now studying a type of tape that has been soaked with **steroids**, which are released slowly into the keloid, causing it to thin over time.

Newer treatments include injections of interferon directly into the keloid, and local application of five percent imiquimod cream, which induces the skin where it is applied to produce interferon. The imiquimod cream is reported to lower the risk of keloid recurrence significantly.

Prognosis

Although keloids are unsightly, they are not life–threatening nor medically dangerous. Keloids do not have a tendency to develop into malignancies, but they can become cosmetically unacceptable. Keloids can gradually lessen after treatment, but many recur. And just as they can occur spontaneously, they can also resolve spontaneously. Over time, many keloids become smaller and less noticeable. When surgery is performed, a scar usually forms at the sight of the keloid. Sometimes the scar is larger in area than the original keloid. Imiquimod cream is now used to minimize the possibilities of keloids forming after surgery. Often, the area surrounding and at the keloid site can become tender and feel uncomfortable to the person. This sensation is often caused by irritation from the rubbing of clothing or other personal articles that the person is wearing.

People who have keloids can prevent them from discoloring by protecting them from sunlight, or using sunblock when exposing them to sunlight.

KEY TERMS

Atrophy—A wasting away of, becoming thinner, less strong.

Corticosteroids—Any of several steroid medications used to suppress inflammation, allergic, or immune responses of the body.

Cryosurgery—The use of extreme cold to kill or remove tissue.

Prevention

Preventive measures include avoiding any **trauma** to the skin, and compression pressure dressing for high-risk patients who have suffered burns to their skin. Proper care of the skin on a daily basis is also important, including the prompt treatment of skin abrasions and cuts. Such treatment includes cleaning the site, applying antibiotic medicine on and around the affected skin, placing a protective dressing over the wound, and applying stitches to the cut if deemed medically necessary. Patients with a tendency to form keloids should avoid any sort of elective surgery. Individuals who are prone to develop keloids or who have a history of keloids should immediately care for any cuts or abrasions they may sustain.

To lower the risk of keloids, surgeons are advised to close incisions with as little tension on the sutures as possible, and to use buried sutures whenever possible.

Close-up of a damaged cornea due to complications following cataract surgery. *(Custom Medical Stock Photo, Inc.)*

Keratitis

Definition

Keratitis is generally the result of an inflammation of the cornea, the transparent dome-shaped membrane that covers the colored part of the eye (iris) and the hole at the center of the iris that allows light to enter the retina (pupil). Keratitis can be the result of an infection caused by bacteria, viruses, fungi, or parasites. However, noninfectious keratitis can be caused by a scratch or abrasion to the eye or by prolonged contact lens usage. Keratitis can also be caused by various medical conditions. Sometimes the cause is unknown that produces corneal inflammation. Keratitis is sometimes also called **corneal ulcers**.

There are differing degrees of keratitis. If only the upper layers of the cornea are involved—a condition known as superficial keratitis—there is usually no permanent damage. However, when keratitis affects the lower layers of the cornea—a condition called deep keratitis—the damage caused may leave a scar in the cornea, thus permanently impairing vision.

Description

There are many types and causes of keratitis. Organisms cannot generally invade an intact, healthy cornea. The 0.002-in. (0.5-mm) thick, 0.5-in. (13 mm) diameter cornea is the dome-shaped membrane located in the front of the eye. The clear cornea allows one to see the iris and pupil. It allows for most of the optical power of the eye (with the remaining smaller portion provided by the lens). However, certain conditions can permit an infection to occur in the cornea. For example, a scratch can leave the cornea open to infection. A very dry eye can also decrease the cornea's protective mechanisms.

Risk factors that increase the likelihood of developing this condition include:

- poor contact lens care; overuse of contact lenses
- illnesses or other factors that reduce the body's ability to overcome infection (compromised immune system, such as from diabetes)
- previous injuries
- cold sores, genital herpes, and other viral infections
- crowded, dirty living conditions; poor hygiene
- warm climates, especially those with high humidity
- corticosteroids that treat eye problems
- poor nutrition (especially a deficiency of vitamin A, which is essential for normal vision)

The various types of keratitis are oftentimes grouped by cause, location, and severity. Some common types of keratitis are herpes simplex keratitis, bacterial keratitis, fungal keratitis, peripheral ulcerative keratitis,

superficial punctate keratitis, *Acanthamoeba* keratitis, photokeratitis, and interstitial keratitis.

Herpes simplex keratitis

A major cause of adult eye disease, herpes simplex keratitis may lead to the following conditions:

- chronic inflammation of the cornea
- development of tiny blood vessels in the eye
- scarring
- loss of vision
- glaucoma

This infection generally begins with inflammation of the membrane lining the eyelid (conjunctiva) and the portion of the eyeball that comes into contact with it. Subsequent infections are characterized by a pattern of lesions that resemble the veins of a leaf. These infections are called dendritic keratitis and aid in diagnosis of the condition.

Recurrences may be brought on by **stress**, **fatigue**, or ultraviolet (UV) light exposure. Repeated episodes of dendritic keratitis can cause sores, permanent scarring, and numbness of the cornea.

Recurrent dendritic keratitis is often followed by disciform keratitis. This condition is characterized by clouding and deep, disc-shaped swelling of the cornea and by inflammation of the iris.

It is very important not to use topical **corticosteroids** with herpes simplex keratitis as it can make the condition much worse, possibly leading to blindness.

Bacterial keratitis

People who have bacterial keratitis wake up with their eyelids stuck together. There can be **pain**, sensitivity to light, redness, tearing, and a decrease in vision. This condition, which is usually aggressive, can be caused by wearing soft **contact lenses** overnight. One study found that overnight wear increases risk by 10 to 15 times more than daily wear. Improper lens care is also a factor. Contaminated makeup can also contain bacteria.

Bacterial keratitis usually is caused by the bacteria *Staphylococcus aureus* and *Pseudomonas aeruginosa* (especially for wearers of contact lenses). The infection makes the cornea cloudy and may also cause abscesses to develop in the stroma, which is located beneath the outer layer of the cornea.

Fungal keratitis

Usually a consequence of injuring the cornea in a farm-like setting or in a place where plant material is present, fungal keratitis often develops slowly. This condition usually affects people with weakened immune systems and often results in infection within the eyeball. It may cause stromal abscesses.

Fungal keratitis is usually caused by the fungus *Aspergillus fumigatus* or by one of many fungus species within the genus *Fusarium*. It can also be caused by species within the yeast genus of *Candida*. The symptoms of fungal keratisis include red, painful eyes, blurred vision, increased sensitivity to light, and excessive discharge around the eye or increased production of tears. The condition usually does not improve when contact lenses are removed or when an antibiotic treatment is used. Fungal keratisis is a relatively rare disorder.

Peripheral ulcerative keratitis

Peripheral ulcerative keratitis is also called marginal keratolysis or peripheral rheumatoid ulceration. This condition is often associated with active or chronic disorders such as the following:

- rheumatoid arthritis
- relapsing polychondritis (connective–tissue inflammation)
- Wegener's granulomatosis, a rare condition characterized by kidney disease and development of nodules in the respiratory tract

Superficial punctate keratitis

Often associated with the type of viruses that causes upper respiratory infection (adenoviruses), superficial punctate keratitis is characterized by destruction of pinpoint areas in the outer layer of the cornea (epithelium). One or both eyes may be affected.

Acanthamoeba keratitis

This pus-producing condition, also called amoebic keratitis, is very painful. It is a common source of infection of the cornea. It is especially troublesome in people who wear soft or rigid contact lenses. This type of keratitis is caused by the bacterium genus *Acanthamoeba*. It can be found in tap water, soil, and swimming pools.

Photokeratitis

Photokeratitis, sometimes also called ultraviolet keratitis or snowblindness, is caused by excess exposure to natural or artificial UV light without proper eye protection. This condition can occur at high altitudes from sunlight reflecting off snow fields or from suntanning lamps or welding arcs. It is very painful because

WWW.BOOKBAZ.IR

it causes a type of **sunburn** to the cornea. The condition may occur several hours after exposure and may last one to two days. In all cases, symptoms include pain in the eyes and increased production of tears.

Interstitial keratitis

Also called parenchymatous keratitis, interstitial keratitis is a chronic inflammation of tissue deep within the cornea. Interstitial keratitis is rare in the United States. Interstitial keratitis affects both eyes and usually occurs as a complication of congenital or acquired **syphilis**. In congenital syphilis, it can occur between the age of two years and **puberty**. It may also happen in people with **tuberculosis**, **leprosy**, or other diseases.

Demographics

Keratitis affects about 50,000 Americans annually. Most of the cases involve people who are afflicted with keratitis more than once. According to the Wilmer Eye Institute at the Johns Hopkins University, keratitis is considered the most common cause of corneal blindness that is caused by infection. The organization states that various types of keratitis exist but "most commonly it occurs after an injury to the cornea, dryness or inflammation of the ocular surface or contact lens wear."

Causes and symptoms

Keratitis has multiple causes. Some of the more common causes are listed below:

- contaminated contact lenses
- bacterial, fungal, or parasitic infections
- viral infections, such as from the herpes virus and other viruses that cause chlamydia
- dry eyes resulting from disorders of the eyelid or diminished ability to form tears
- exposure to very bright light
- contaminated water
- foreign object injury
- upper respiratory infection
- sensitivity or allergic reactions
- vitamin A deficiency

Symptoms of keratitis include, but are not limited to the following:

- difficulty opening eyelids
- excessive tearing or discharge from eyes
- pain in and around eyes
- swelling of eyes
- itchy or burning feeling in eyes
- feeling of foreign object in eye
- sensitivity to light
- inflammation of the eyelid
- decrease in vision
- redness of the eyes

Diagnosis

For a patient's initial diagnosis, a case history is be taken and vision is tested by the eye doctor, usually an ophthalmologist. Examination with a slit lamp, a microscope that focuses a beam of light on the eye, is important for diagnosis. The cornea can be examined with fluorescein, a yellow dye that highlights defects in the cornea. Deeper layers of the cornea can also be analyzed with the slit lamp. The doctor can see infiltrates, hazy looking areas in the cornea. These observations aid in the diagnosis. Samples of infectious matter removed from the eye can be sent for laboratory analysis.

Treatment

Antibiotic, antifungal, or antiviral oral medication are used to treat the appropriate organism. Broad-spectrum **antibiotics** are used immediately, but once the laboratory analysis determines the offending organism, the medication may be changed to pinpoint the intruder. Sometimes using more than one medication is necessary.

A sterile, cotton-tipped applicator may be used to gently remove infected tissue and allow the eye to heal rapidly. **Laser surgery** is sometimes performed to destroy unhealthy cells, with some severe infections requiring corneal transplants.

Antifungal, antibiotic, or antiviral eye drops or ointments are usually prescribed for keratitis, but they should be used only by patients under a doctor's care. Inappropriate prescriptions or over-the-counter preparations can make symptoms more severe and cause tissue deterioration. Topical corticosteroids can cause great harm to the cornea in patient's with herpes simplex keratitis.

A patient with keratitis may wear a patch to protect the healing eye from bright light, **foreign objects**, the lid rubbing against the cornea, and other irritants. The patient will probably return every day to the eye doctor to check on the progress.

Although early detection and treatment can cure most forms of keratitis, the infection can cause:

- glaucoma
- permanent scarring
- ulceration of the cornea
- blindness

KEY TERMS

Abscess—A collection of pus.

Glaucoma—An eye disease characterized by an increase of pressure in the eye. Left untreated, blindness may result.

Infiltrate—A collection of cells not usually present in a given area. In the cornea, infiltrates may be a collection of white blood cells.

Inflammation—A localized response to an injury, which may include swelling, redness, and pain.

Prognosis

When treated promptly and effectively, keratitis can be corrected without loss of vision. However, when minor cases of keratitis are left untreated, they can lead to serious complications that may permanently damage or eliminate vision in the eyes. Such complications include chronic or recurrent viral infections of the cornea, corneal swelling or scarring, blindness, open corneal sores, and chronic corneal inflammation.

Prevention

Contact lenses should only be worn as recommended by an eye care professional and cleaned using sterile lens-cleaning and disinfecting solutions. Tap water is not sterile and should not be used to clean contact lenses. Always wash, rinse, and dry one's hands before handling contact lenses. It is important to go for follow-up checkups because small defects in the cornea can occur without the patient being aware of it. Remove lenses if eyes become red or irritated. Replace contact lenses as scheduled. Proteins and other materials can be deposited on the contacts, leading to an increased risk of infection. Clean contact lens cases as directed and replace contact lens cases every three months. Do not wear contact lenses while swimming or in a hot tub.

Eating a well-balanced diet and wearing protective glasses when working or playing in potentially dangerous situations can reduce anyone's risk of developing keratitis. Protective goggles should be worn while mowing the lawn so that if twigs and other debris are tossed up they cannot hurt the eyes. Goggles or sunglasses with UV coatings can help protect against damage from ultraviolet light.

Avoid touching the eyes if one has an infection, such as a cold sore, to prevent infection within the eyes. Discontinue wearing contact lenses if keratitis occurs frequently. Minimize the use of corticosteroid eye drops, which increase the risks of viral infections.

REVISED BY WILLIAM A. ATKINS, BB, BS, MBA

Keratosis pilaris

Definition

Keratosis pilaris is a common skin condition that looks like small, rough goose bumps (patches), which are actually dead skin cells that build up around the hair follicle. Also called follicular keratosis, or simply KP, it is a commonly found follicular condition that most frequently appears on the back and outer sides of

WWW.BOOKBAZ.IR

the upper arms, thighs, and buttocks. KP can also be located on the lower arms, hands, legs, and lower back. It never appears on the soles of the feet or the palms of the hands. It is rarely present on the face. When it does appear on the face (especially on the cheeks), KP is commonly mistaken for **acne**. It is also described as "chicken bumps" and "chicken skin." Although the appearance of keratosis pilaris on the body is not desirable, it does not pose a medical risk. It is considered to be completely harmless to the human body.

Demographics

KP can be contracted by anyone all over the world but it is often considered a fairly common condition of children and adolescents. Consequently, more adolescents are at risk for it (about 50–80% worldwide) than are adults (about 40%). It is also more commonly found on women than it is on men. It appears equally in all races. Generally, KP improves with age. About 30–50% of people who have keratosis pilaris also have a family history for it. People who are obese or have troubling long-term health issues are at increased risk for contracting KP. However, people of normal weight and otherwise good health have also been found to have keratosis pilaris.

Description

Keratosis pilaris is called a hyperkeratinization of the skin because the buildup of keratin on the skin is thought by the medical community to cause the rough bumps and the overall poor skin appearance that characterize the condition. For people with KP, the process called keratinization is defective; that is, the formation of the epidermal skin is not normal, which causes bumps to form. Why this happens is not known to medical professionals, although various assumptions have been made as to why keratosis pilaris occurs on some people but not on others.

KP is a disorder that occurs around the hair follicles of the upper and lower arms, hands, lower back, thighs, legs, and sometimes the buttocks. It presents as small, benign bumps or papules that are actually waxy build-ups of keratin. Normally the skin sloughs (sheds) them off. However, around the hair follicle where the papules form, the keratinized skin cells slough off at a slower rate, clogging the follicles.

The disorder is generally thought to be genetic in nature, although the symptoms of keratosis pilaris are often seen with **ichthyosis** (a disease in which the skin becomes dry, scaly and thick) and allergic **dermatitis** (a form of dermatitis associated with an allergic reaction). It is also observed in people of all ages who have inherited the condition or who have a **vitamin A** deficiency or dry skin. Keratosis pilaris is a self-limiting disorder that usually disappears as the person ages. It can become more severe when conditions are dry such as during the winter months or in dry, arid climates.

A localized area on the skin may show an appearance of between 10 to 100 bumps that may give the area a sandpaper-looking appearance. Some of the bumps may appear slightly red in color, which indicates that they are inflamed. Most bumps are white in color, and are from one to two millimeters in diameter.

Causes and symptoms

The specific causes of this disorder are unknown. However, they are known to exist as keratin builds up. Keratin is a hard protein that helps to protect the skin from infections and harmful substances. When keratin builds up it forms a scaly plug that blocks the opening to the hair follicle. These blockages cause the small, rough bumps associated with keratosis pilaris. Since this disorder sometimes runs in families, it is thought to be a hereditary condition, one in which people have a genetic predisposition for it. If one child has KP then his or her siblings seem to be more likely to acquire it, too, especially among children of multiple births. Keratosis pilaris is not a serious disorder and is not contagious. Dry skin seems to make the condition worsen. Consequently, cold winter months are more troublesome for people with KP than are the warm summer months.

The symptoms of keratosis pilaris are based on the development of small white papules (or acne-like bumps) the size of a grain of sand on the upper arms, thighs, and occasionally the buttocks and face. The papules occur around a hair follicle and are firm and white. They feel a little like coarse sandpaper (that is, like dry, rough patches of skin), but they are not usually painful and **itching** is not usually associated with them. They are sometimes reddish in color, which indicates inflammation. They are easily removed and the material inside the papule usually contains a small, coiled hair.

Diagnosis

The diagnosis for keratosis pilaris is often made by a dermatologist or physician while making a **physical examination** of unrelated skin conditions. Laboratory tests or skin tests have yet to be developed to identify keratosis pilaris. A medical professional can easily diagnose this disorder by examining the skin

KEY TERMS

Benign—Not cancerous.

Dermatologist—A physician who specializes in diseases and disorders of the skin.

Ichthyosis—A group of congenital disorders of keratinization characterized by dryness and scaling of the skin.

Keratin—The hard, waxy material that is made by the outer layer of skin cells.

and reviewing the patient's medical history and family background with respect to skin conditions. During the physical examination, the physician looks for the signs and symptoms associated with KP.

Treatment

There is no cure for keratosis pilaris. It is treatable but usually the treatment is difficult. To treat keratosis pilaris patients can try several strategies to lessen the bumps. First, the patient can supplement the natural removal of dry skin and papules by using a loofah or another type of scrub for showering or bathing. A mild cleanser is recommended. A long-term skin care program that is used regularly seems to produce the best results. Sometimes several skin care plans are used in combination to produce more desirable results.

Most of the treatment options center around (1) topical exfoliants, including medicated creams that include alpha-hydroxy, lactic or salicylic acids, or urea, which moisturize and soften dry skin and remove dead skin cells; (2) topical **corticosteroids**, such as hydrocortisone type substances, which suppress the immune system and decrease the production of skin cells; and (3) topical retinoids, such as tretinoin and tazarotene, which increase the production of skin cells and help to prevent the plugging up of hair follicles.

A variety of different over-the-counter (OTC) lotions, ointments, and creams can also be applied after showering while the skin is still moist and then used several times a day to keep the area moist. Medicated lotions with urea, 15% alpha hydroxy acids, or tretinoin (Retin A) can also be prescribed by the dermatologist and applied one to two times daily. Systemic (oral) medications are not prescribed for keratosis pilaris. However if papules are opened and become infected, **antibiotics** may be necessary to treat the infection.

Lactic acid lotions such as AmLactin and Lac–Hydrin may be prescribed. In addition, salicylic acid (Salex lotion or cream) and topical steroid creams (triamcinolone acetonide 0.1%, or hydrocortisone butyrate [Locoid Lipocream]) may also be prescribed as possible treatments for KP. Sometimes, these lotions are manufactured so they combine more than one of these ingredients in case the prescribing physician or dermatologist uses combination plans. Many other treatment options are also available. Each should be used only under the direction of a physician.

Sometimes minor surgical procedures are used for keratosis pilaris when KP persists even though multiple treatments have been attempted. Gentle acne extraction is one such procedure that can help to correct the problem. Microdermabrasion is another procedure that can be performed, usually in an in–office environment. The procedure exfoliates the skin with a gentle rubbing of abrasive particles (such as aluminum crystals) along with the lifting off the extracted skin with a vacuum. Chemical peels (a chemical solution to remove the top layer of dead skin), **photodynamic therapy** (PDT, consisting of a photosensitizer, light, and tissue oxygen), blue-light lasers (which emits electromagnetic radiation at a wavelength of between 360 and 480 nanometers), and intense pulsed light (IPL) instruments (which produce electromagnetic radiation at high intensities for very short periods) are also used as treatments. Other procedures are also available. It is always important that such procedures are used with the approval and under the direction of a physician.

Prognosis

Unfortunately, the treatment for keratosis pilaris is often disappointing. Although extreme cases of keratosis pilaris can occasionally be unsightly, the disorder is not life threatening and usually begins to disappear as the patient ages. Overall, however, many cases resolve themselves as the person gets older. KP usually disappears by the age of 30 years. In others, the problem persists with chronic reoccurrences and remissions of keratosis pilaris. Although treatment of keratosis pilaris is often frustrating to the patient, prescription medications and skin care measures can improve the appearance of the affected skin areas with consistency and persistence.

Prevention

Since keratosis pilaris is thought to be a genetic disorder and is observed in several members of the same family, there is nothing that can be done to prevent

WWW.BOOKBAZ.IR

this disorder. Following the treatment advice above can alleviate the outward characteristics of keratosis pilaris. Mild soaps and cleansers help to minimize the problem. Do not aggressively rub the skin because such action will irritate the condition. When washing and bathing or showering, use warm water. Hot water dries the skin more. Keep a bath or shower to less than 15 minutes in duration. Gently dry off with a patting motion, and do not use harsh rubbing motions. The regular application of emollients is also helpful. Preventing dry skin is also recommended. Use a moisturizing lotion or lubricating cream on a regular basis, especially right after drying off from washing. The application of lactic acid, an over–the–counter product, has been shown to help remove excess keratin from the skin. Maintain humidified air within the home to avoid dry air, which will aggravate the problem.

Sally C. McFarlane–Parrott

Kidney biopsy

Definition

Kidney biopsy is a medical procedure in which a small piece of tissue is removed from the kidney for microscopic examination.

Purpose

The test is usually done to diagnose **kidney disease** and to evaluate the extent of damage to the kidney. A biopsy is also frequently ordered to detect the reason for acute renal failure when normal office procedures and tests fail to establish the cause. In addition, information regarding the progression of the disease and how it is responding to medical treatment can be obtained from a biopsy. Occasionally a biopsy may be done to confirm a diagnosis of **kidney cancer**, to determine its aggressiveness, and decide on the mode of treatment.

Precautions

The biopsy is not recommended for patients who have any uncontrollable bleeding disorders. Platelets are blood cells that play an important role in the blood clotting process. If the bleeding disorder is caused by a low **platelet count** (less than 50,000 per cubic millimeter of blood), then a platelet **transfusion** can be done just before performing the biopsy.

Description

The kidneys, a pair of organsas shaped like kidney beans that are lie on either side of the backbone, just above the waist. The periphery (parenchyma) of the kidney is made up of tiny tubes. These tubes filter and clean the blood by taking out the waste products and making urine. The urine is collected in the central portion of the kidney. Tubes called ureters drain the urine from the kidney into the bladder, where it is held until it is voided from the body.

A kidney specialist (nephrologist) performs the biopsy. It can be done either in the doctor's office or in a local hospital. The patient may be given a calming drug before the procedure to help him relax. The skin and muscles on the back overlying the site that is to be biopsied may be numbed with local **anesthesia**.

The patient will be asked to lie face down and a pad or a rolled towel may be placed under the stomach. Either the left or the right kidney may be biopsied depending on the results of the imaging tests: x rays, **computed tomography scans** (CT scans), **magnetic resonance imaging** (MRI), and **ultrasound**. The area that will be biopsied is cleaned with an antiseptic solution and sterile drapes are placed on it. The skin is numbed with local anesthesia. A small incision is made on the skin with a scalpel blade. Using a long needle, the physician injects local anesthesia into the incision so that it infiltrates down to the kidney. The biopsy needle is then advanced slowly through the incision. The patient is asked to hold his or her breath

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Computed tomography (CT) scan—A medical procedure in which a series of x rays are taken and put together by a computer in order to form detailed pictures of areas inside the body.

Magnetic resonance imaging (MRI)—A medical procedure used for diagnostic purposes in which pictures of areas inside the body can be created using a magnet linked to a computer.

Nephrologist—A doctor who specializes in the diseases and disorders of the kidneys.

Renal ultrasound—A painless and non-invasive procedure in which sound waves are bounced off the kidneys. These sound waves produce a pattern of echoes that are then used by the computer to create pictures of areas inside the kidney (sonograms).

each time the needle is pushed forward. Once the wall (capsule) of the kidney has been penetrated, the patient can breathe normally. The tissue is collected for examination and the needle is withdrawn. The needle may be re-inserted into another part of the kidney so that tissue is collected from at least three different areas. The tissue samples are sent to the laboratory for examination. The entire procedure may last about an hour.

Preparation

Before performing the biopsy, the doctor should be made aware of all the medications that the patient is taking. The doctor should also be told whether the patient is allergic to any medications. The procedure and the risks of the procedure are explained to the patient and the necessary consent forms are obtained. The patient should be told that a kidney biopsy requires a 24-hour stay in the hospital after the biopsy.

Some doctors order blood tests to check for clotting problems before performing the biopsy. The patient's blood type may also be determined in case a transfusion becomes necessary.

Aftercare

Immediately after the biopsy, pulse, respiration, and temperature (vital signs) are measured. If they are stable, the patient is instructed to lie flat in bed for at least 12 hours. The pulse and blood pressure are checked at regular intervals by the nursing staff. All urine voided by the patient in the first 12–24 hours is examined in the laboratory for blood cells.

If bleeding is severe, iron levels in the blood drop significantly, or the patient complains of severe **pain** at the biopsy site, the physician should be contacted immediately. After the patient goes home, he should avoid heavy lifting, vigorous **exercise**, and contact sports for at least one or two weeks.

Results

The results are normal if no abnormalities can be seen in the tissue samples with the naked eye, with an electron microscope or through staining with a fluorescent dye (immunofluorescence).

Risks

The risks of a kidney biopsy are very small. Severe bleeding may occur after the procedure. There is also a slight chance that an infection or a lump of blood under the skin that looks black and blue (hematoma) may develop. In most cases, the hematoma disappears by itself and does not cause any pain. However, severe pain or a drop in blood pressure and iron levels in the blood indicates that the hematoma is expanding. This condition could lead to complications and should be reported immediately to the doctor.

Very rarely, the patient may develop high blood pressure (**hypertension**), and the bleeding may be severe enough to require a transfusion. In extremely rare circumstances, the kidney may rupture, or the surrounding organs (pancreas, bowel, spleen, and liver) may be punctured. Death occurs in about one in 3000 cases.

Abnormal results

Any abnormalities in the size, color, and consistency of the sample will be reported as an abnormal result. In addition, any change in the structure of the renal tubules, the presence of red blood cells, or abnormalities in the cells are considered an abnormal result. If cancerous changes are detected in the kidney cells, they are further characterized in order to determine

WWW.BOOKBAZ.IR

the stage of the tumor and decide on the appropriate mode of treatment.

Lata Cherath, PhD

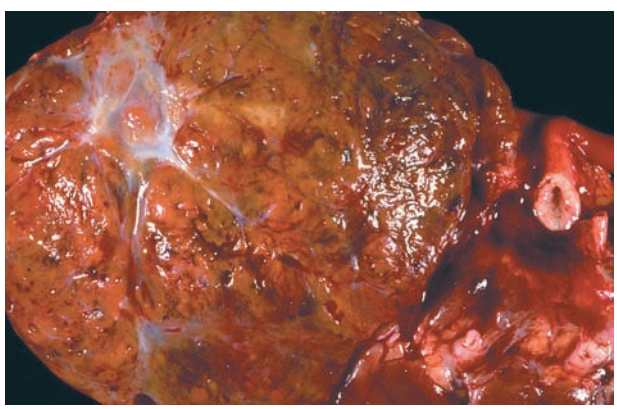
Kidney cancer

Definition

Kidney cancer is a disease in which the cells in certain tissues of the kidney start to grow uncontrollably and form tumors. Renal cell carcinoma, which occurs in the cells lining the kidneys (epithelial cells), is the most common type of kidney cancer. Eighty-five percent of all kidney tumors are renal cell carcinomas. Wilms' tumor is a rapidly developing cancer of the kidney most often found in children under four years of age.

Description

The kidneys are a pair of organs that lie on either side of the spine just above the waist. Inside each kidney are tiny tubes (tubules) that filter and clean the blood, taking out the waste products and making urine. The urine that is made by the kidney passes through a tube called the ureter into the bladder. Urine is held in the bladder until it is discharged from the body. Renal cell carcinoma generally develops in the lining of the tubules that filter and clean the blood. Cancer that develops in the central portion of the kidney (where the urine is collected and drained into the ureters) is known as transitional cell cancer of the renal pelvis. Transitional cell cancer is similar to **bladder cancer**.



An extracted cancerous kidney. *(Custom Medical Stock Photo, Inc.)*

Kidney cancer accounts for approximately 2–3% of all cancers. In the United States, kidney cancer is the tenth most common cancer and the incidence has increased by 43% since 1973; the death rate has increased by 16%. According to the American Cancer Society, 63,920 Americans were diagnosed with kidney cancer in 2014, and 13,860 died from the disease. RCC accounts for 90–95% of malignant neoplasms that originate from the kidney.

Causes and symptoms

The causes of kidney cancer are unknown, but men seem to have a greater risk than women of contracting the disease. There is a strong association between cigarette **smoking** and kidney cancer. Cigarette smokers are twice as likely as non-smokers are to develop kidney cancer. Working around coke ovens has been shown to increase people's risk of developing this cancer. Certain types of painkillers that contain the chemical phenacetin are associated with kidney cancer. The United States government discontinued use of **analgesics** containing phenacetin in the 1990s. **Obesity** may be yet another risk factor for kidney cancer. Some studies show a loose association between kidney cancer and occupational exposure to cadmium, petroleum products, lead, dry-cleaning solvents, trichloroethylene (TCE), and asbestos. Other risk factors for the development of kidney cancer include Hispanic heritage and preexisting von Hippel-Lindau disease.

The most common symptom of kidney cancer is blood in the urine (hematuria). Other symptoms include painful urination, **pain** in the lower back or on the sides, abdominal pain, a lump or hard mass that can be felt in the kidney area, unexplained weight loss, **fever**, weakness, **fatigue**, and high blood pressure.

Other symptoms may occur if the cancer has spread beyond its original location. Spread of kidney cancer most commonly occurs to the lung (55%), liver (33%), bone (33%), adrenal (20%), and opposite kidney (10%). Lymph node spread is also common, occurring in about 25% of patients).

Diagnosis

A diagnostic examination for kidney cancer includes taking a thorough medical history and making a complete **physical examination** in which the

doctor will probe (palpate) the abdomen for lumps. Blood tests will be ordered to check for changes in blood chemistry caused by substances released by the tumor. Laboratory tests may show abnormal levels of iron in the blood. Either a low red blood cell count (anemia) or a high red blood cell count (erythrocytosis) may accompany kidney cancer. Occasionally, patients will have high **calcium** levels.

If the doctor suspects kidney cancer, an intravenous pyelogram (IVP) may be ordered. An IVP is an x-ray test in which a dye in injected into a vein in the arm. The dye travels through the body, and when it is concentrated in the urine to be discharged, it outlines the kidneys, ureters, and the urinary bladder. On an x-ray image, the dye will reveal any abnormalities of the urinary tract. The IVP may miss small kidney cancers.

Renal **ultrasound** is a diagnostic test in which sound waves are used to form an image of the kidneys. Ultrasound is a painless and non-invasive procedure that can be used to detect even very small kidney tumors. Imaging tests such as **computed tomography scans** (CT scans) and **magnetic resonance imaging** (MRI) can be used to evaluate the kidneys and the surrounding organs. These tests are used to check whether the tumor has spread outside the kidney to other organs in the abdomen. If the patient complains of bone pain, a special x ray called a **bone scan** may be ordered to rule out spread to the bones. A chest x ray may be taken to rule out spread to the lungs.

A **kidney biopsy** is used to positively confirm the diagnosis of kidney cancer. During this procedure, a small piece of tissue is removed from the tumor and examined under a microscope. The biopsy will give information about the type of tumor, the cells that are involved, and the aggressiveness of the tumor (tumor stage).

Treatment

Each person's treatment is different and depends on several factors. The location, size, and extent of the tumor have to be considered in addition to the patient's age, general health, and medical history. In addition, much has changed in the treatment and management of kidney cancer since the 1980s, including new surgical techniques, new **anticancer drugs**, and the development of effective treatments for advanced disease.

The primary treatment for kidney cancer that has not spread to other parts of the body, which is a Stage I, II, or III tumor, is surgical removal of the diseased kidney (**nephrectomy**). Because most cancers affect only one kidney, the patient can function well with the remaining one. Two types of surgical procedure are used. Radical nephrectomy removes the entire kidney and the surrounding tissue. Sometimes, the lymph nodes surrounding the kidney are also removed. Partial nephrectomy removes only part of the kidney along with the tumor. This procedure is used either when the tumor is very small or when it is not practical to remove the entire kidney. It is not practical to remove a kidney when the patient has only one kidney or when both kidneys have tumors. There is a small (5%) chance of missing some of the cancer. Nephrectomy can also be useful for Stage IV cancers, but alternative surgical procedures such as transarterial angioinfarction may be used.

The rapid development and widespread use of laparoscopic techniques has made it possible for surgeons to remove small tumors while sparing the rest of the kidney. Most tumors removed by **laparoscopy** are 4 cm (1.6 in) in size or smaller. Laparoscopy also allows the surgeon to remove small tumors with cryoablation (destroying the tumor by freezing it) rather than cutting.

Radiation therapy, which consists of exposing the cancer cells to high-energy gamma rays from an external source, generally destroys cancer cells with minimal damage to the normal tissue. Side effects are nausea, fatigue, and stomach upsets. These symptoms disappear when the treatment is over. In kidney cancer, radiation therapy has been shown to alleviate pain and bleeding, especially when the cancer is inoperable. However, it has not proven to be of much use in destroying the kidney cancer cells. Therefore radiation therapy is not used very often as a treatment for cancer or as a routine adjuvant to nephrectomy. Radiotherapy, however, is used to manage metastatic kidney cancer.

Treatment of kidney cancer with anticancer drugs (**chemotherapy**) has not produced good results. However, new drugs and new combinations of drugs continue to be tested in clinical trials. One new drug, semaxanib (SU5416), is reported to have good results in treating patients with kidney cancer. However, semaxanib is considered an experimental drug and further development was suspended. In 2006, a similar drug called sunitinib (SU11248) was approved for use.

Immunologic therapy (or immunotherapy), a form of treatment in which the body's immune system is harnessed to help fight the cancer, is a new mode of therapy that is being tested for kidney cancer. Clinical trials with substances produced by the immune cells (aldesleukin and interferon) have shown some promise in destroying kidney cancer cells. These substances have been approved for use but they can be very toxic and produce severe side effects. The benefits derived from the treatment have to be weighed very

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Bone scan—An x-ray study in which patients are given an intravenous injection of a small amount of a radioactive material that travels in the blood. When it reaches the bones, it can be detected by x ray to make a picture of their internal structure.

Chemotherapy—Treatment with anticancer drugs.

Computed tomography (CT) scan—A medical procedure in which a series of x-ray images are made and put together by a computer to form detailed pictures of areas inside the body.

Cryoablation—A technique for removing tissue by destroying it with extreme cold.

Hematuria—Blood in the urine.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

Intravenous pyelogram (IVP)—A procedure in which a dye is injected into a vein in the arm. The dye travels through the body and concentrates in the urine to be discharged. It outlines the kidneys, ureters, and the urinary bladder. An x-ray image is then made and any abnormalities of the urinary tract are revealed.

Magnetic resonance imaging (MRI)—A medical procedure used for diagnostic purposes in which pictures of areas inside the body can be created using a magnet linked to a computer.

Nephrectomy—A medical procedure in which the kidney is surgically removed.

Radiation therapy—Treatment with high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Renal ultrasound—A painless and non-invasive procedure in which sound waves are bounced off the kidneys. These sound waves produce a pattern of echoes that are then used by the computer to create pictures of areas inside the kidney (sonograms).

carefully against the side effects in each case. Immunotherapy is the most promising systemic therapy for metastatic kidney cancer.

Prognosis

Because kidney cancer is often caught early and sometimes progresses slowly, the chances of a surgical cure are good. Length of survival depends on the size of the original tumor, the aggressiveness of the specific cells making up the tumor, and whether the cancer cells spread from the kidney to surrounding or distant tissues.

Kidney cancer is also one of the few cancers for which there are well-documented cases of spontaneous remission without therapy. Unfortunately, recurrences can occur even as long as ten years after the original diagnosis and treatment, and cancer can also crop up in the other, previously unaffected kidney.

Prevention

The exact cause of kidney cancer is not known, so it is not possible to prevent all cases. However, because a strong association between kidney cancer and tobacco has been shown, avoiding tobacco is the best way to lower one's risk of developing this cancer. Using care when working with cancer-causing agents such as asbestos and cadmium and eating a well-balanced diet may also help prevent kidney cancer.

Kidney dialysis

Definition

Dialysis treatment replaces the function of the kidneys, which normally serve as the body's natural filtration system. Through the use of a blood filter and a chemical solution known as dialysate, the treatment removes waste products and excess fluids from the bloodstream, while maintaining the proper chemical balance of the blood. There are two types of dialysis treatment: hemodialysis and peritoneal dialysis.

Purpose

Dialysis is prescribed for patients with temporary or permanent kidney failure. People with end-stage renal disease (ESRD) have kidneys that are no longer capable of adequately removing fluids and wastes from their body or of maintaining the proper level of certain kidney-regulated chemicals in the bloodstream. For these individuals, dialysis is the only treatment option available outside of **kidney transplantation**. Dialysis may also be used to simulate kidney function in patients awaiting a transplant until a donor kidney becomes available. Also, dialysis may be used in the treatment of patients suffering from **poisoning** or overdose in order to quickly remove drugs from the bloodstream.

Demographics

Hemodialysis and peritoneal dialysis have been performed since the mid-1940s. As a regular treatment for patients, kidney dialysis was begun in 1960. Thousands of patients have been helped by these treatments. In the early part of the twenty-first century, the incidence of chronic **kidney disease** (CKD) was increasing most rapidly in people aged 65 years and older. In fact, the reported incidences of CKD in people ages 65 years and older have more than doubled between the years 2000 and 2008. As of 2014, the vast majority of kidney dialysis patients—over 350,000 Americans in all who have end stage renal disease (ESRD)—have their treatments performed at medical centers. Only 8% of US dialysis patients treat themselves at home. According to the National Kidney and Urologic Diseases Information Clearinghouse (NKUDIC), at the end of 2009, 398,861 ESRD patients were being treated with some type of kidney dialysis. In addition, more than ten times as many ESRD patients receive hemodialysis (HD) treatments at a medical clinic when compared to those who perform peritoneal dialysis (PD) and home dialysis (HD) combined.

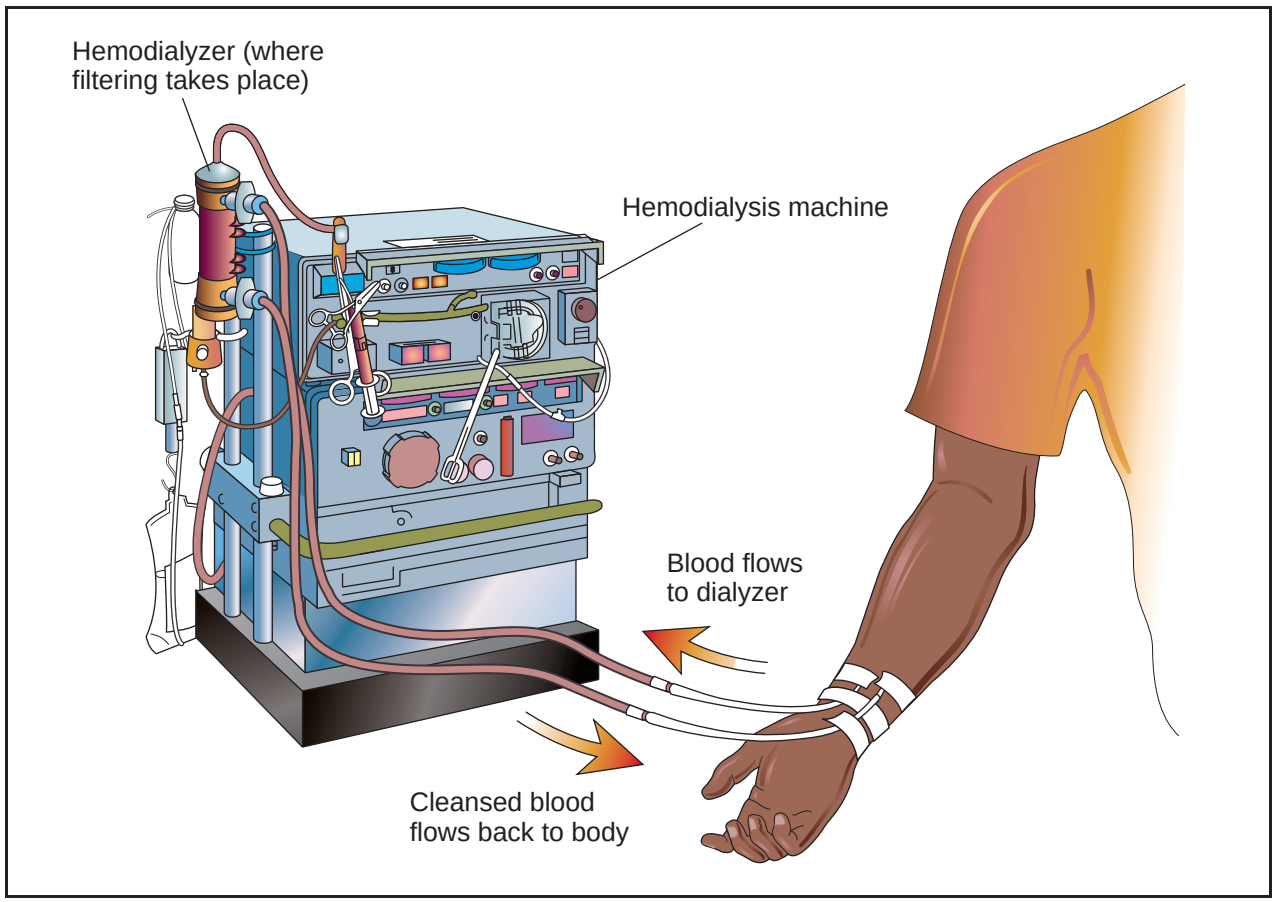
As of the latest reports available, **diabetes mellitus** is the leading single cause of ESRD: 40% of dialysis patients in the United States have ESRD caused by diabetes, 28% by **hypertension**, 11.6% by **glomerulonephritis**, and 4.7% by cystic (bladder) or other urologic conditions.

Among children and young adults (under 20 years of age) on dialysis, glomerulonephritis is the leading cause of ESRD (31%), and hereditary, cystic, and congenital diseases account for 37%. Pediatric patients typically spend less time on dialysis than adults; according to the USRDS, the average waiting period for a kidney transplant for patients under the age of 20 years is 10 months, compared to the adult wait of approximately two years.

Description

Dialysis treatment and regimen is usually overseen by a nephrologist (a doctor that specializes in the kidneys). The hemodialysis treatment itself is

WWW.BOOKBAZ.IR



Hemodialysis is the most frequently prescribed type of dialysis treatment in the United States. This treatment involves circulating the patient's blood outside of the body through a dialysis circuit. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

typically administered by a nurse or patient care technician in outpatient clinics known as dialysis centers, or in hospital-based dialysis units. In-home hemodialysis treatment is also an option for some patients, although access to this type of treatment may be limited by financial and lifestyle factors. An investment in equipment is required and another person in the household should be available for support and assistance with treatments. Peritoneal dialysis is also performed at home by the patient, perhaps with the aide of a home healthcare worker.

There are two types of dialysis treatment: hemodialysis and peritoneal dialysis.

Hemodialysis

Hemodialysis is the most frequently prescribed type of dialysis treatment in the United States. The treatment involves circulating the patient's blood outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. Two needles are inserted into the patient's vein, or access site, and are attached to the ECC, which consists of plastic blood tubing, a filter known as a dialyzer (artificial kidney), and a dialysis machine that monitors and maintains blood flow and administers dialysate. Dialysate is a chemical bath that is used to draw waste products out of the blood.

Since the 1980s, the majority of hemodialysis treatments in the United States have been performed with hollow fiber dialyzers. A hollow fiber dialyzer is composed of thousands of tube-like hollow fiber strands encased in a clear plastic cylinder several inches in diameter. There are two compartments within the dialyzer (the blood compartment and the dialysate compartment).

The membrane that separates these two compartments is semipermeable. This means that it allows the passage of certain sized molecules across it, but prevents the passage of other, larger molecules. As blood is pushed through the blood compartment in

one direction, suction or vacuum pressure pulls the dialysate through the dialysate compartment in a countercurrent, or opposite direction. These opposing pressures work to drain excess fluids out of the bloodstream and into the dialysate, a process called ultrafiltration.

A second process called diffusion moves waste products in the blood across the membrane and into the dialysate compartment, where they are carried out of the body. At the same time, electrolytes and other chemicals in the dialysate solution cross the membrane into the blood compartment. The purified, chemically balanced blood is then returned to the body.

Most hemodialysis patients require treatment three times a week, for an average of three to four hours per dialysis "run." Specific treatment schedules depend on the type of dialyzer used and the patient's current physical condition.

Blood pressure changes associated with hemodialysis may pose a risk for patients with heart problems. Peritoneal dialysis may be the preferred treatment option in these cases.

Peritoneal dialysis

In peritoneal dialysis, the patient's peritoneum, or lining of the abdomen, acts as a blood filter. A catheter is surgically inserted into the patient's abdomen. During treatment, the catheter is used to fill the abdominal cavity with dialysate. Waste products and excess fluids move from the patient's bloodstream into the dialysate solution. After a waiting period of six to 24 hours, depending on the treatment method used, the waste-filled dialysate is drained from the abdomen and replaced with clean dialysate.

There are three types of peritoneal dialysis:

- Continuous ambulatory peritoneal dialysis (CAPD) is a continuous treatment that is self-administered and requires no machine. The patient inserts fresh dialysate solution into the abdominal cavity, waits four to six hours, and removes the used solution. The solution is immediately replaced with fresh dialysate. A bag attached to the catheter is worn under clothing.
- Continuous cyclic peritoneal dialysis (CCPD), also called automated peritoneal dialysis (APD), is an overnight treatment that uses a machine to drain and refill the abdominal cavity. CCPD takes 10 to 12 hours per session.
- Intermittent peritoneal dialysis (IPD) is a hospital-based treatment that is performed several times a week. A machine administers and drains the dialysate solution, and sessions can take 12 to 24 hours.

Peritoneal dialysis is often the treatment option of choice in infants and children, whose small size can make vascular (through a vein) access difficult to maintain. Peritoneal dialysis can also be performed outside of a clinical setting, which is more conducive to regular school attendance.

Peritoneal dialysis is not recommended for patients with abdominal **adhesions** or other abdominal defects, such as a **hernia**, that might compromise the efficiency of the treatment. It is also not recommended for patients who suffer frequent bouts of **diverticulitis**, an inflammation of small pouches in the intestinal tract.

Preparation

Patients are weighed immediately before and after each hemodialysis treatment to evaluate their fluid retention. Blood pressure and temperature are taken and the patient is assessed for physical changes since their last dialysis run. Regular blood tests monitor chemical and waste levels in the blood. Prior to treatment, patients are typically administered a dose of heparin, an anticoagulant that prevents blood clotting, to ensure the free flow of blood through the dialyzer and an uninterrupted dialysis run for the patient.

Aftercare

Both hemodialysis and peritoneal dialysis patients need to be vigilant about keeping their access sites and catheters clean and infection-free during and between dialysis runs.

Dialysis is just one facet of a comprehensive treatment approach for ESRD. Although dialysis treatment is very effective in removing toxins and fluids from the body, there are several functions of the kidney it cannot mimic, such as regulating high blood pressure and red blood cell production. Patients with ESRD need to watch their dietary and fluid intake carefully and take medications as prescribed to manage their disease.

Results

Because dialysis is an ongoing treatment process for many patients, a baseline for normalcy can be difficult to gauge. Puffiness in the patient related to **edema**, or fluid retention, may be relieved after dialysis treatment. The patient's overall sense of physical well-being may also be improved.

Monthly blood tests to check the levels of urea, a waste product, help to determine the adequacy of the dialysis prescription. Another test, called Kt/V (dialyzer clearance multiplied by time of treatment and divided by the total volume of water in the patient's

WWW.BOOKBAZ.IR

body), is also performed to assess patient progress. A urea reduction ratio (URR) of 65% or higher, and a Kt/V of at least 1.2 are considered the benchmarks of dialysis adequacy by the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation. Both the Kt/V and the URR determine whether the kidney dialysis treatments are removing sufficient amounts of wastes. They analyze the level of blood urea nitrogen (BUN), which is a good indicator for the overall level of waste products within the body.

Morbidity and mortality rates

The U.S. Renal Data System (USRDS), which is a national data system that collects, analyzes, and distributes information about ESRD, reports that mortality rates for individuals on dialysis are significantly higher than both kidney transplant patients and the general population. The organization also reports that the expected remaining lifetimes of chronic dialysis patients are only one-fourth to one-fifth that of the general population. The NKUDIC states that the five-year survival rate for kidney transplant patients (85.5%) is more than twice the rate for dialysis patients (35.8%). In addition, the hospitalization rates for ESRD patients are four times greater than that of the general U.S. population.

Risks

Many of the risks and side effects associated with dialysis are a combined result of both the treatment and the poor physical condition of the ESRD patient. Dialysis patients should always report side effects to their healthcare provider.

Anemia

Hematocrit (Hct) levels, a measure of red blood cells, are typically low in ESRD patients. This deficiency is caused by a lack of the hormone erythropoietin, which is normally produced by the kidneys. The problem is elevated in hemodialysis patients, who may incur blood loss during hemodialysis treatments. Epoetin alfa, or EPO (sold under the trade name Epogen), a hormone therapy, and intravenous or oral iron supplements are used to manage anemia in dialysis patients.

Cramps, nausea, vomiting, and headaches

Some hemodialysis patients experience cramps and flu-like symptoms during treatment. These can be caused by a number of factors, including the type of dialysate used, composition of the dialyzer membrane, water quality in the dialysis unit, and the ultrafiltration rate of the treatment. Adjustment of the dialysis prescription often helps alleviate many symptoms.

Hypotension

Because of the **stress** placed on the cardiovascular system with regular hemodialysis treatments, patients are at risk for **hypotension**, a sudden drop in blood pressure. This can often be controlled by medication and adjustment of the patient's dialysis prescription.

Infection

Both hemodialysis and peritoneal dialysis patients are at risk for infection. Hemodialysis patients should keep their access sites clean and watch for signs of redness and warmth that could indicate infection. Peritoneal dialysis patients must follow the same precautions with their catheter. **Peritonitis**, an infection of the peritoneum, causes flu-like symptoms and can disrupt dialysis treatments if not caught early.

Infectious diseases

Because there is a great deal of blood exposure involved in dialysis treatment, a slight risk of contracting **hepatitis B** and **hepatitis C** exists. The hepatitis B **vaccination** is recommended for most hemodialysis patients. Very few documented cases of HIV being transmitted in a U.S. dialysis unit to a staff member have been reported, and there were no documented cases as of 2013 of HIV being transmitted between dialysis patients in the United States. The strict standards of **infection control** practiced in modern hemodialysis units minimize the chance of contracting one of these diseases.

Alternatives

The only alternative to dialysis for ESRD patients is a successful kidney transplant. However, demand for donor kidneys has traditionally far exceeded supply. As of January 20, 2015, there were 101,557 patients on the U.S. Department of Health and Human Services' Organ Procurement and Transplantation Network (OPTN) waiting list for a kidney transplant. In 2014, about 24,383 kidney transplants were performed in the United States.

For patients with diabetes, the number one cause of **chronic kidney failure** in adults, the best way to avoid ESRD and subsequent dialysis is to maintain tight control of blood glucose levels through diet, **exercise**, and medication. Controlling high blood pressure is also important.

KEY TERMS

Access site—The vein tapped for vascular access in hemodialysis treatments. For patients with temporary treatment needs, access to the bloodstream is gained by inserting a catheter into the subclavian vein near the patient's collarbone. Patients in long-term dialysis require stronger, more durable access sites, called fistulas or grafts, that are surgically created.

Dialysate—A chemical bath used in dialysis to draw fluids and toxins out of the bloodstream and supply electrolytes and other chemicals to the bloodstream.

Dialysis prescription—The general parameters of dialysis treatment that vary according to each patient's individual needs. Treatment length, type of dialyzer and dialysate used, and rate of ultrafiltration are all part of the dialysis prescription.

Dialyzer—An artificial kidney, usually composed of hollow fiber, that is used in hemodialysis to eliminate waste products from the blood and remove excess fluids from the bloodstream.

Erythropoietin—A hormone produced by the kidneys that stimulates the production of red blood cells by bone marrow.

ESRD—End-stage renal disease; chronic or permanent kidney failure caused by disease, disorder, or congenital condition.

Extracorporeal circuit (ECC)—The path the hemodialysis patient's blood takes outside of the body. It typically consists of plastic tubing, a hemodialysis machine, and a dialyzer.

Glomerulonephritis—A disease of the kidney that causes inflammation and scarring and impairs the kidney's ability to filter waste products from the blood.

Hematocrit (Hct) level—A measure of red blood cells.

Peritoneum—The abdominal cavity; the peritoneum acts as a blood filter in peritoneal dialysis.

Kidney disease

Definition

Kidney disease is a general term for any damage that reduces the functioning of the kidney. Kidney disease is also called renal disease.

Description

The kidneys are a pair bean-shaped, fist-sized organs that are located below the rib cage near the middle of the back. In adults they filter about 200 quarts (190 L) of blood every day to remove waste products that result from the normal activities of tissues in the body. These wastes circulate in the blood. and if not removed they would damage the body. The kidneys also play a crucial role in regulating the amount of water and chemicals (electrolytes) in the body such as **sodium**, potassium and phosphorous.

Inside the kidneys are about one million tiny units called nephrons. Inside each nephron is a very thin blood vessel called a capillary that twists around a very thin tube called a tubule. This combination of capillary and tubule inside the nephron is called a glomerulous and it is here that the blood is filtered. Water, electrolytes, and waste products (but not red blood cells) can pass across the capillary wall and into the tubule. The kidney then regulates how much water and which other substances can pass back into the blood in the capillary to keep the body in balance. Waste products, excess water, and excess electrolytes remain in the tubule and eventually leave the body as urine.

The kidneys also release three regulatory chemicals—erythropoietin, renin, and calcitriol—that affect other functions in the body. Erythropoietin stimulates the bone marrow to produce new red blood cells. Renin helps regulate blood pressure, and calcitriol is a form of **vitamin D** and is important in maintaining bones and the level of **calcium** in the body.

Because the kidney has many functions, there are many types of kidney disease. Congenital kidney diseases are disorders that are present at birth. **Polycystic kidney disease** (PKD) is a rare disorder in which children inherit defective genes from both parents that cause cysts full of fluid to develop in the kidneys and replace the blood filtering units. As a result, the kidneys cannot adequately remove wastes from the body. There are two other types of PDK. One is inherited, but does not appear until adulthood, and the other develops as a result of long-term kidney damage. In total, about half a million people in the United States have some form of PKD. Hereditary disease and **birth defects** are the most common causes of kidney disease in children up to age 14.

Acute kidney diseases are problems that develop suddenly. Many acute kidney diseases can be cured, but some may cause permanent damage. Common acute kidney diseases include kidney infection, hemolytic uremic syndrome, **nephrotic syndrome** in children, and damage caused by injury to the kidney or **poisoning**. Hemolytic uremic syndrome is a rare disease that usually affects children under age ten and is caused by eating food contaminated with bacteria. The bacteria release a poison that damages the kidney and causes **acute kidney failure**. Most children who develop this disease recover and their kidney function returns to normal.

Chronic kidney disease is disease that is slow to develop and usually does not show any symptoms until kidney damage is permanent. The National Kidney and Urologic Disease Information Clearinghouse, a federal agency, estimates that about 4.5% of people over age 20 have chronic kidney disease as indicated by tests that measure kidney function. The most common cause of chronic kidney disease in the United States is diabetes. It accounts for between 33% and 40% of all new cases of chronic kidney disease in the United States. In diabetes, the body cannot break down glucose (sugar). This extra glucose in the blood damages the nephrons so that they no longer filter blood effectively.

High or uncontrolled blood pressure (**hypertension**) is the second leading cause of chronic kidney disease. It accounts for between 27% and 30% of all new cases of chronic kidney disease. High blood pressure damages the capillaries in the nephron, so that they can no longer work with the tubules to filter the blood. Glomerulonephtitis is a term for several different chronic kidney diseases where damage to the nephrons causes protein or red blood cells pass into the urine. **Kidney cancer** is uncommon, accounting for only 2% of cancer cases.

Over-the-counter **analgesics** (**pain** medications) such as **aspirin**, **acetaminophen** (Tylenol), ibuprofen (Advil), naxopren sodium (Aleve), and similar medications that can be bought without a prescription may make kidney disease worse in individuals who already have kidney damage or cause kidney damage in healthy individuals who take these medications daily for several years. The chance of damage is increased when these pain medications are taken in combination with each other or with **caffeine** or codeine (Some painkilling tablets are a combination of pain medications and caffeine or codeine). Individuals who take

these painkillers regularly or who have been told they have kidney damage should discuss the risk of these medications with their physician.

Chronic kidney disease can lead to end-stage renal disease (ESRD), in which there is almost total failure of the kidneys. If renal function is reduced to only 25% of normal, serious illness results. When this drops to 10–15% of normal, death occurs unless the individual receives dialysis or a kidney transplant. In 2002, there were over 100,300 new cases of ESRD, 44% of which were caused by diabetes. Treatment of ESRD in the United States cost about $25.2 billion in 2002.

Causes and symptoms

Causes of kidney disease are many and varied. Leading causes are diabetes, high blood pressure, inherited disease, and infection. Acute kidney disease is often marked by a lack of urination and increased fluid build up in the body. Chronic kidney disease is often called a "silent" killer, because no obvious symptoms develop until the kidneys are permanently damaged. The National Kidney Foundation estimated in 2014 that 26 million Americans had undetected moderate chronic kidney disease. Chronic kidney disease most often results from other diseases such as diabetes or hypertension.

Diagnosis

Simple blood and urine tests can indicated kidney disease, but more extensive testing may be needed to determine the exact nature of the disease. A blood test that measures serum creatinine, a waste product, can indicate how well the kidneys are working. Although normal levels of creatinine vary (an average range is 0.6–1.2 mg/dL), a higher than expected level in the blood may indicate kidney damage. A blood urea nitrogen (BUN) blood test measures waste products circulating in the blood. Normal levels range from 7%–20 mg/dL. The less well the kidney is working, the higher the BUN.

A 24-hour urine collection test will accurately measure how much urine the kidneys are producing in a day. A **urinalysis** can determine if protein or red blood cells are leaking into the urine indicating abnormal kidney function. A creatinine clearance test compares the amount of creatinine in a 24-hour urine sample with the amount of creatinine in the blood to determine how much blood the kidneys are filtering each minute.

Based on the results of blood and urine tests, other tests such as a CT scan, MRI, or **kidney biopsy** may be ordered.

Treatment

Most treatment for kidney disease involves treating the underlying cause of the disease, such as controlling high blood pressure or diabetes. Diuretic medication ("water pills") may be given to help relieve fluid accumulation. **Antibiotics** are used to treat kidney infections. Other drugs may be given to treat specific kidney diseases.

Diet and lifestyle changes are an important part of controlling kidney disease. **Obesity** increases blood pressure, so losing weight can help limit kidney damage, as can stopping **smoking**. Reducing sodium (salt) in the diet also helps control blood pressure. In certain kinds of kidney disease, potassium is removed in abnormally large quantities by the kidneys and excreted in urine. Eating more foods such as bananas, dried beans and peas, nuts, and potatoes that are high in potassium or taking a potassium supplement pill help reverse this effect. When protein is found in the urine, some physicians recommend reducing the amount of protein (mainly found in meat) in the diet.

When kidneys fail completely in ESRD, there are only two alternatives: dialysis or kidney transplant. There are two types of dialysis. Peritoneal dialysis uses a membrane in the individual's abdomen to filter waste products. The most common kind of peritoneal dialysis is continuous ambulatory peritoneal dialysis (CAPD), in which the individual is hooked up to a bag of dialysis fluid that he carries with him, allowing continuous dialysis. The fluid is changed four times a day. In another form of peritoneal dialysis, the abdomen is filled with dialysis fluid. Wastes filter into the fluid for several hours often while the individual is asleep, the then the fluid is drained from the body. Peritoneal dialysis can be done at home without the need for a health care professional.

In hemodialysis, the individual must go to a dialysis center about three times a week. His blood is sent through a machine that filters out the waste and then returns the cleansed blood to his body. The process takes three to four hours and is done by a health care professional.

Kidney transplants can come from either a living donor or a deceased donor. Donors are matched with recipients based on blood type and must take drugs to prevent their immune system from rejecting the kidney after transplantation. The United Network for Organ Sharing (UNOS) coordinates matching donor kidneys with appropriate recipients. More than 100 clinical trials are enrolling patients with various types of kidney disease.

WWW.BOOKBAZ.IR

KEY TERMS

Congenital—Present at birth.

Diuretic—A substance that stimulates the kidney to excrete water.

Glomerulous—A twisted mass of blood capillaries and urine tubules in the kidney where filtering of waste products occurs.

Hormone—A chemical produced by living cells that travels through the circulatory system and affects tissue at some distance from where it was released.

Hypertension—High blood pressure.

Nephron—The smallest functional unit of the kidney involved in the removal of waste products and excess water from the blood.

Alternatives

Alternative treatments tend to focus on removing excess water from the body, but have limited effect on serious disease. Asparagus (*Asparagus officinalis*) birch tea (*Betula* species), goldenrod infusion (*Solidago* species), horsetail (*Equisetum arvense*), and stinging nettle (*Urtica dioica*) all are used to stimulate urine production.

Prognosis

Many individuals recover normal kidney function after developing acute kidney disease, although in some cases, such as poisoning and injury, kidney damage may be permanent. Chronic kidney disease tends to get progressively worse as the individual ages. More than 15,000 kidney transplants are done each year, and there is a often long waiting list for donated kidneys. 80.6% of individuals receiving a transplant from a deceased donor survive for at least 5 years, and 90.4% of individuals receiving a kidney donated from a living donor survive for at least 5 years.

Prevention

Maintaining a healthy body weight, getting regular **exercise**, and not smoking all promote kidney health. Controlling underlying diseases such as diabetes and high blood pressure are important in preventing chronic kidney diseases.

Kidney function tests

Definition

Kidney function tests include a variety of individual tests and procedures that can be done to evaluate how well the kidneys are functioning. A doctor who orders kidney function tests and uses the results to assess the functioning of the kidneys is called a nephrologist.

Purpose

The kidneys, the body's natural filtration system, perform many vital functions, including removing metabolic waste products from the bloodstream, regulating the body's water balance, and maintaining the pH (acidity/alkalinity) of the body's fluids. Approximately one and a half quarts of blood per minute are

circulated through the kidneys, where waste chemicals are filtered out and eliminated from the body (along with excess water) in the form of urine. Kidney function tests help to determine if the kidneys are performing their tasks adequately.

Precautions

The doctor should take a complete history prior to conducting kidney function tests to evaluate the patient's food and drug intake. A wide variety of prescription and over-the-counter medications can affect blood and urine kidney function test results, as can some food and beverages.

Description

Many conditions can affect the ability of the kidneys to carry out their vital functions. Some conditions can lead to a rapid (acute) decline in kidney function; others lead to a gradual (chronic) decline in function. Both can result in a buildup of toxic waste substances in the blood. A number of clinical laboratory tests that measure the levels of substances normally regulated by the kidneys can help to determine the cause and extent of kidney dysfunction. Urine and blood samples are used for these tests.

The nephrologist uses these results in a number of ways. Once a diagnosis is made that **kidney disease** is present and what kind of kidney disease is causing the problem, the nephrologist may recommend a specific treatment. Although there is no specific drug therapy that will prevent the progression of kidney disease, the doctor will make recommendations for treatment to slow the disease as much as possible. For instance, the doctor might prescribe blood pressure medications or treatments for patients with diabetes. If kidney disease is getting worse, the nephrologist may discuss hemodialysis (blood cleansing by removal of excess fluid, **minerals**, and wastes) or **kidney transplantation** (surgical procedure to implant a healthy kidney into a patient with kidney disease or kidney failure) with the patient.

Laboratory tests

There are a number of urine tests that can be used to assess kidney function. A simple, inexpensive screening test—a routine urinalysis—is often the first test conducted if kidney problems are suspected. A small, randomly collected urine sample is examined physically for things like color, odor, appearance, and concentration (specific gravity); chemically, for substances such as protein, glucose, and pH (acidity/alkalinity); and microscopically for the presence of cellular elements (red blood cells [RBCs], white blood cells [WBCs], and epithelial cells), bacteria, crystals, and casts (structures formed by the deposit of protein, cells, and other substances in the kidneys's tubules). If results indicate a possibility of disease or impaired kidney function, one or more of the following additional tests is usually performed to pinpoint the cause and the level of decline in kidney function.

- Creatinine clearance test. This test evaluates how efficiently the kidneys clear a substance called creatinine from the blood. Creatinine, a waste product of muscle energy metabolism, is produced at a constant rate that is proportional to the individual's muscle mass. Because the body does not recycle it, all creatinine filtered by the kidneys in a given amount of time is excreted in the urine, making creatinine clearance a very specific measurement of kidney function. The test is performed on a timed urine specimen—a cumulative sample collected over a 2 to 24-hour period. Determination of the blood creatinine level is also required to calculate the urine clearance.
- Urea clearance test. Urea is a waste product that is created by protein metabolism and excreted in the urine. The urea clearance test requires a blood sample to measure the amount of urea in the bloodstream and two urine specimens, collected one hour apart, to determine the amount of urea that is filtered, or cleared, by the kidneys into the urine.
- Urine osmolality test. Urine osmolality is a measurement of the number of dissolved particles in urine. It is a more precise measurement than specific gravity for evaluating the ability of the kidneys to concentrate or dilute the urine. Kidneys that are functioning normally will excrete more water into the urine as fluid intake is increased, diluting the urine. If fluid intake is decreased, the kidneys excrete less water and the urine becomes more concentrated. The test may be done on a urine sample collected first thing in the morning, on multiple timed samples, or on a cumulative sample collected over a 24-hour period. The patient will typically be prescribed a high-protein diet for several days before the test and be asked to drink no fluids the night before the test.
- Urine protein test. Healthy kidneys filter all proteins from the bloodstream and then reabsorb them, allowing no protein, or only slight amounts of protein, into the urine. The persistent presence of significant amounts of protein in the urine, then, is an important indicator of kidney disease. A positive screening test for protein (included in a routine urinalysis) on a random urine sample is usually followed up with a test on a 24-hour urine sample that more precisely measures the quantity of protein.

WWW.BOOKBAZ.IR

There are also several blood tests that can aid in evaluating kidney function. These include:

- Blood urea nitrogen test (BUN). Urea is a byproduct of protein metabolism. Formed in the liver, this waste product is then filtered from the blood and excreted in the urine by the kidneys. The BUN test measures the amount of nitrogen contained in the urea. High BUN levels can indicate kidney dysfunction. Since BUN is also affected by protein intake and liver function, the test is usually done together with a blood creatinine, a more specific indicator of kidney function.
- Creatinine test. This test measures blood levels of creatinine, a byproduct of muscle energy metabolism that, similar to urea, is filtered from the blood by the kidneys and excreted into the urine. Production of creatinine depends on a person's muscle mass, which usually fluctuates very little. With normal kidney function, the amount of creatinine in the blood remains relatively constant and normal. For this reason, and because creatinine is affected very little by liver function, an elevated blood creatinine level is a more sensitive indicator of impaired kidney function than the BUN.
- Other blood tests. Measurement of the blood levels of other elements regulated in part by the kidneys can also be useful in evaluating kidney function. These elements include sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphorus, protein, uric acid, and glucose.

Results

Normal values for many tests are determined by the patient's age and gender. Reference values can also vary by laboratory.

Urine tests

Values are generally within the following ranges:

- Creatinine clearance. For a 24-hour urine collection, normal results are 90–139 mL/min for adult males younger than 40 and 80–125 mL/min for adult females younger than 40. For people over 40, values decrease by 6.5 mL/min for each decade of life.
- Urine osmolality. With restricted fluid intake (concentration testing), osmolality should be greater than 800 mOsm/kg of water. With increased fluid intake (dilution testing), osmolality should be less than 100 mOSm/kg in at least one of the specimens collected. A 24-hour urine osmolality should average 300–900 mOsm/kg. A random urine osmolality should average 500–800 mOsm/kg.
- Urine protein. A 24-hour urine collection should contain no more than 150 mg of protein.
- Urine sodium. A 24-hour urine sodium should be within 75–200 mmol/day.

Blood tests

Values are generally within the following ranges:

- Blood urea nitrogen (BUN) should average 8–20 mg/dL.
- Creatinine should be 0.8–1.2 mg/dL for males and 0.6–0.9 mg/dL for females.
- Uric acid levels should be 3.5–7.2 mg/dL for males and 2.6–6.0 mg/dL for females.

Low clearance values for creatinine indicate a diminished ability of the kidneys to filter waste products from the blood and excrete them in the urine. As clearance levels decrease, blood levels of creatinine, urea, and uric acid increase. Because it can be affected by other factors, an elevated BUN alone is suggestive, but not diagnostic, for kidney dysfunction. An abnormally elevated plasma creatinine is a more specific indicator of kidney disease than is BUN.

Low clearance values for creatinine and urea indicate a diminished ability of the kidneys to filter these waste products from the blood and to excrete them in the urine. As clearance levels decrease, blood levels of creatinine and urea nitrogen increase. Since it can be affected by other factors, an elevated BUN alone is certainly suggestive for kidney dysfunction. However, it is not diagnostic. An abnormally elevated blood creatinine, a more specific and sensitive indicator of kidney disease than the BUN, is diagnostic of impaired kidney function.

The inability of the kidneys to concentrate the urine in response to restricted fluid intake, or to dilute the urine in response to increased fluid intake during osmolality testing, may indicate decreased kidney function. Because the kidneys normally excrete almost no protein in the urine, its persistent presence in amounts that exceed the normal 24-hour urine value usually indicates some type of kidney disease.

Patient education

Some kidney problems are the result of another disease process, such as diabetes or **hypertension**. Doctors should take the time to inform patients about how their disease or its treatment will affect kidney function, as well as the different measures patients can take to help prevent these changes.

KEY TERMS

Blood urea nitrogen (BUN)—The nitrogen portion of urea in the bloodstream. Urea is a waste product of protein metabolism in the body.

Creatinine—The metabolized by-product of creatine, an organic compound that assists the body in producing muscle contractions. Creatinine is found in the bloodstream and in muscle tissue. It is removed from the blood by the kidneys and excreted in the urine.

Creatinine clearance rate—The clearance of creatinine from the plasma compared to its appearance in the urine. Since there is no reabsorption of creatinine, this measurement can estimate glomerular filtration rate.

Diuretic—A drug that increases the excretion of salt and water, increasing the output of urine.

Kilogram—Metric unit of weight equal to 1,000 grams or 2.2046 lb.

Nephrologist—A doctor who specializes in kidney disease.

Osmolality—A measurement of urine concentration that depends on the number of particles dissolved in it. Values are expressed as milliosmols per kilogram (mOsm/kg) of water.

Specific gravity—The ratio of the weight of a body fluid when compared with water.

Urea—A by-product of protein metabolism that is formed in the liver. Because urea contains ammonia, which is toxic to the body, it must be quickly filtered from the blood by the kidneys and excreted in the urine.

Uric acid—A product of purine breakdown that is excreted by the kidney. High levels of uric acid, caused by various diseases, can cause the formation of kidney stones.

Urine—A fluid containing water and dissolved substances excreted by the kidney.

Kidney nuclear medicine scan

Definition

A kidney nuclear medicine scan, or study, is a simple outpatient test that involves administering small amounts of radioactive substances, called tracers, into the body and then imaging the kidneys and

WWW.BOOKBAZ.IR

bladder with a special camera. The images obtained can help in the diagnosis and treatment of certain kidney diseases.

Purpose

While many tests, such as x rays, **ultrasound** exams, or **computed tomography scans** (CT scans), can reveal the structure of the kidneys (its anatomy), the kidney nuclear medicine scan is unique in that it reveals how the kidneys are functioning. This is valuable information in helping a doctor make a diagnosis. Therefore, the kidney nuclear medicine scan is performed primarily to see how well the kidneys are working and, at the same time, they can identify some of the various structures that make up the kidney.

Precautions

If a patient is pregnant, it is generally recommended that she not have a kidney nuclear medicine scan. The unborn baby is more sensitive to radiation than an adult. If a woman thinks she might be pregnant, she should inform her doctor of this too.

Women who are **breastfeeding** should also inform their doctor. The doctor may recommend the woman stop breastfeeding for a day or two after a kidney nuclear medicine scan, depending on the particular tracer that was used since the tracer can accumulate in breast milk.

Description

Nuclear medicine is a branch of **radiology** that uses radioactive materials to diagnose or treat various diseases. These radioactive materials (tracers) may also be called radiopharmaceuticals, and they accumulate (collect) in specific organs in the body. Radiopharmaceuticals are able to yield valuable information about the particular organ being studied.

Whether outside the body or inside the body, tracers emit radioactive signals, called gamma rays, which can be collected and counted by a special device, called a gamma camera. The images of the kidney that the camera produces are called renal scans.

The kidney nuclear medicine scan can be performed on an outpatient basis, usually by a nuclear medicine technologist. The technologist helps prepare the patient for the exam by positioning him or her on an exam table or cart in the imaging area. The patient's position is usually flat on the back. The patient must lie still during imaging to prevent blurring of the images that will be taken. The technologist positions the camera as close to the kidney (or kidneys) as possible to obtain the best images.

In the next step of the procedure, the technologist injects the radiopharmaceutical into the patient. This may be done with one single injection or through an intravenous (IV) line. Immediately after the tracer is injected, imaging begins. It is important to obtain images right away because the tracer's radioactivity begins to diminish (decay). The time required for one-half of the tracer's activity to decay is called the tracer's half-life (T 1/2). The half-life is unique to each radiopharmaceutical. Also, it is important to see the kidney in its immediate state.

Serial pictures are taken with the gamma camera and may be seen on a computer or TV-like screen. The camera doesn't emit radiation, it only records it. The images then are stored on film.

A kidney nuclear medicine scan ranges from 45 minutes to three hours in length, depending on the goals of the test. But the test typically takes about an hour to an hour-and-a-half.

Once the images and curves are obtained, the nuclear medicine physician or radiologist analyzes, or reads, them. Various information can be provided to the doctor through these, depending on the test that was performed. A variety of kidney nuclear medicine studies are available for a doctor to help in making diagnoses. It is important to understand that kidney nuclear medicine scans are good at identifying when there is an abnormality, but they do not always identify the specific problem. They are very useful in providing information about how the various parts of the kidneys function, which, in turn, can assist in making a diagnosis.

Studies may be performed to determine the rate at which the kidney's are filtering a patient's blood. These studies use a radiopharmaceutical, called Technetium DTPA (Tc 99m DTPA). This radiopharmaceutical also can identify obstruction (blockage) in the collecting system. To study how well the tubules and ducts of the kidney are functioning, the radiopharmaceutical Technetium MAG3 is used. Studying tubular function is a good indicator of overall renal function. In many renal diseases, one of the first things that disappears or diminishes is the tubular function.

Candidates for a kidney nuclear medicine scan are patients who have:

- Renal failure or chronic renal failure
- Obstruction in their urine collection systems
- Renal artery stenosis
- A kidney transplant.

KEY TERMS

Intravenous pyelogram (IVP)—X-ray technique using dye to image the kidneys, ureters, and bladder.

Renal—Having to do with the kidneys.

Renal artery stenosis—Narrowing or constriction of the artery that supplies the kidney with blood.

Preparation

No preparation is necessary for a kidney nuclear medicine scan. The doctor may ask the patient to refrain from certain medications, however, before the scan if the medications might interfere with the test. For example, if a scan is being performed to study **renal artery stenosis**, the patient may have to refrain from taking medications for **hypertension**.

Aftercare

Patients can resume their normal daily activities immediately after the test. Most tracers are passed naturally from the body, though drinking fluids after a kidney nuclear medicine scan can help flush the tracer into the urine and out of the body more quickly.

Results

The test reveals normal kidney function for age and medical situation.

Abnormal results

The test reveals a change in function that may be attributable to a disease process, such as obstruction or a malfunctioning kidney. If the test is abnormal, the patient may be recalled another day for a repeat study, performed differently, to narrow the list of causes.

Risks

Nuclear medicine procedures are very safe. Unlike some of the dyes that may be used in x-ray studies, radioactive tracers rarely cause side effects. There are no long-lasting effects of the tracers themselves, because they have no functional effects on the body's tissues.

Kidney removal *see* **Nephrectomy**

Kidney stones

Definition

Kidney stones are solid accumulations of material that form in the tubal system of the kidney. Kidney stones cause problems when they block the flow of urine within the kidney or urinary tract. When the stones move through the ureter, they can cause severe **pain**.

Description

Urine is formed by the kidneys. Blood flows into the kidneys, and nephrons (specialized tubes) within the kidneys allow a certain amount of fluid from the blood, along with certain substances dissolved in that fluid, to flow out of the body as urine. Sometimes, a problem causes the dissolved substances to become solid again. Tiny crystals then form in the urine, meet, and cling together to create a larger solid mass called a kidney stone.

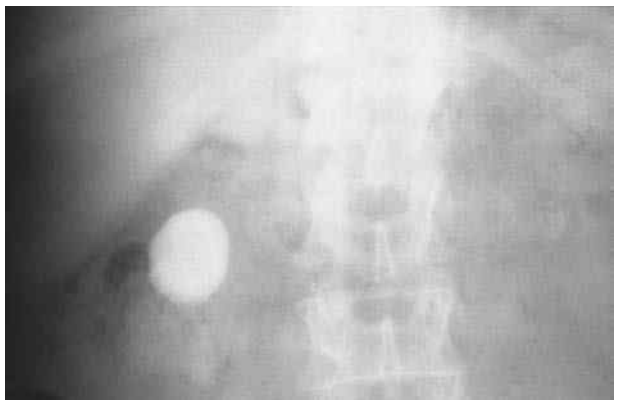
Many kidney stones are small enough that the kidney continues to function normally, and the stones never cause any pain. These are called "silent stones." Kidney stones cause problems when they interfere with the normal flow of urine. They can obstruct (block) the flow through the ureter. The kidney is not accustomed to experiencing any pressure. When pressure builds from backed-up urine, the kidney may swell (**hydronephrosis**). If the kidney is subjected to this pressure for some time, there may be damage to delicate kidney structures. When the kidney stone is lodged further down the ureter, the backed-up urine may also cause the ureter to swell (hydroureter). Because the ureter is a muscular tube, the presence of a stone makes the tube spasm, causing severe pain.

About 10% of all people have a significant kidney stone during their lifetime. Kidney stones are most common among white men over age 30, people who have previously had kidney stones, and people whose family members are prone to developing kidney stones. Eating a lot of animal protein and drinking too few fluids are also thought to contribute to the development of kidney stones.

Causes and symptoms

Kidney stones can be composed of a variety of substances. The most common types of kidney stones are described here.

WWW.BOOKBAZ.IR



X ray of kidney stone. *(Custom Medical Stock Photo, Inc.)*

Calcium stones

About 80% of all kidney stones are **calcium** stones. These stones are composed of either calcium and phosphate, or calcium and oxalate. People with calcium stones may have other diseases that cause them to have increased blood levels of calcium. These diseases include primary parathyroidism, **sarcoidosis**, **hyperthyroidism**, **renal tubular acidosis**, **multiple myeloma**, hyperoxaluria, and some types of cancer.

Struvite stones

Struvite stones account for 10% of all kidney stones. Struvite stones are composed of magnesium ammonium phosphate. These stones occur most often in patients who have had repeated urinary tract infections caused by certain types of bacteria. These bacteria produce a substance called urease that increases the urine pH and makes the urine more alkaline. This chemical environment allows struvite to settle out of the urine, forming stones.

Uric acid stones

About 5% of all kidney stones are uric acid stones. These occur when increased amounts of uric acid circulate in the bloodstream. When the uric acid content becomes very high, it can no longer remain dissolved and solid particles of uric acid settle out of the urine. A kidney stone is formed when these particles cling to each other within the kidney, slowly forming a solid mass. About half of all patients with this type of stone also have deposits of uric acid elsewhere in their bodies, commonly in the joint of the big toe. This painful disorder is called **gout**. Other causes of uric acid stones include **chemotherapy** for cancer, bone marrow disorders in which certain types of blood cells are over-produced, and an inherited disorder called **Lesch-Nyhan syndrome**.

Cystine stones

Cystine stones account for 2% of all kidney stones. Cystine is a type of amino acid, and people with this type of kidney stone have an abnormality in the way their bodies process amino acids in the diet.

Patients who have kidney stones usually do not have symptoms until the stone passes into the ureter. Before this, some people may notice blood in their urine. Once the stone is in the ureter, however, most people experience bouts of very severe pain. The pain is crampy, spasmodic, and intense. It usually begins in the flank region, the area between the lower ribs and the hip bone. As the stone moves closer to the bladder, a patient will often feel the pain radiating along the inner thigh. Women may feel the pain in the vulva, while men often feel pain in the testicles. Nausea, **vomiting**, frequent and painful urination, and blood in the urine are common. **Fever** and chills usually mean that the ureter has become obstructed, allowing bacteria to become trapped in the kidney and cause a kidney infection (**pyelonephritis**).

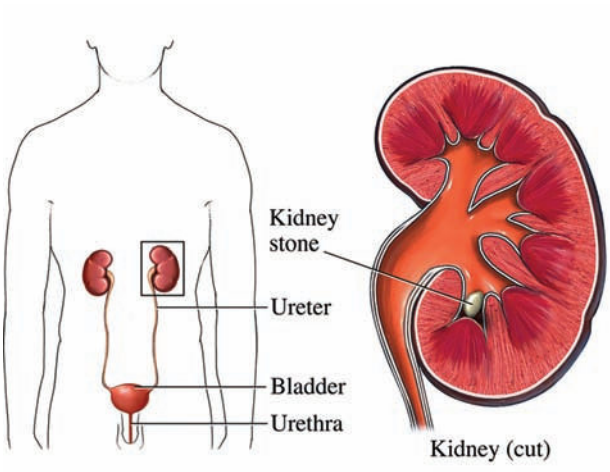
Diagnosis

Most often in a healthy adult, diagnosis of kidney stones is based on the patient's pattern of severe, distinctive pain. Diagnosis may include laboratory examination of a urine sample and an x-ray examination. During the passage of a stone, examination of the urine usually reveals blood. A number of imaging tests can, if necessary, be used to diagnose kidney stones. A plain x ray of the kidneys, ureters, and bladder may or may not reveal the stone. An **ultrasound** can also be used to detect renal blockage. The use of computed tomography (CT) scans has been added to diagnose of some kidney stones.

When a patient is passing a kidney stone, the urine is strained through a special sieve to catch the stone. If the stone can be located (often it cannot), it can then be sent to a laboratory for analysis to determine the chemical composition of the stone. After the kidney stone has been passed, other tests may be done to understand the underlying condition that may have caused the stone to form. Collecting urine for 24 hours, followed by careful analysis of its chemical makeup, can often determine the reason for stone formation.

Treatment

It is believed that stones will pass more quickly if the patient is encouraged to drink large amounts of



Kidney stones can occur in the ureter near the bladder or kidney. *(© Nucleus Medical Art, Inc./Alamy.)*

water (2–3 quarts per day). Cranberry (*Vaccinium macrocarpon*) juice has been a traditional remedy for the treatment and prevention of kidney stones. Although clinical trials have found that cranberry juice has some effect on urinary tract infections, its effectiveness in treating kidney stones is unproven.

Herbal remedies that have anti-lithic (stone-dissolving) action can assist in dissolving small kidney stones. These include gravel root (*Eupatorium purpureum*), hydrangea (*Hydrangea aborescens*), and wild carrot (*Daucus carota*). Starfruit (*Averrhoa carambola*) is recommended to increase the amount of urine a patient passes and to relieve pain.

A Chinese herbal practitioner may use herbs such as *Semen Abutili seu Malvae, Semen plantaginis,* and *Herba lygodii japonici* for urinary stones. Dietary changes can be made to reduce the risk of future stone formation and to facilitate the resorption of existing stones. Supplementation with magnesium, a smooth muscle relaxant, can help reduce pain and facilitate stone passing. **Guided imagery** may also be used to help relieve pain. Large stones may require conventional medical intervention.

The pain associated with a kidney stone sends most patients to the emergency room, and a patient with a kidney stone will say that the most important aspect of treatment is adequate pain relief. Because the pain of passing a kidney stone is so severe, narcotic pain medications are usually required. If the patient is vomiting or unable to drink fluids because of the pain, it may be necessary to provide intravenous fluids and anti-emetics (drugs that stop vomiting). If symptoms and urine tests indicate the presence of infection, **antibiotics** are required.

Although most kidney stones pass on their own, some do not. The preferred method of treatment is extracorporeal shock wave **lithotripsy** (ESWL). Shock waves are aimed at the stone. The energy of the shock waves causes the stone to vibrate and fragment into small pieces that can be more easily passed. This procedure is generally done under light **anesthesia** because the shock waves cause pain. If the stone is lodged in the ureter, the urologist may insert a device into the ureter that can direct laser or ultrasound energy at the stone and pulverize it. If the stone is large and ESWL does not work, the stone may be removed by **minimally invasive surgery**.

Expected results

A patient's prognosis depends on the underlying disorder causing the development of kidney stones. In most cases, patients with uncomplicated calcium stones recover very well. About 60% of these patients, however, will have other kidney stones. Struvite stones are particularly dangerous because they may grow extremely large, filling the tubes within the kidney. These are called staghorn stones and will not pass out in the urine. They require surgical removal. Uric acid stones may also become staghorn stones.

Prognosis

Prevention of kidney stones depends on the type of stone and the presence or absence of an underlying disease. In almost all cases, increasing fluid intake so that a person consistently drinks 2 to 3 quarts (liters) of water a day is an important preventative measure. Drinking a glass of lemonade made with real lemons or real lemon concentrate also helps increase the amount of citrate in the urine. Citrate makes it more difficult for kidney stones to form.

People with calcium oxalate stones do not need to reduce the amount of calcium in their diet but may reduce the amount of foods containing oxalate. These foods include rhubarb, star fruit, beets, beet greens, collards, okra, refried beans, spinach, Swiss chard, sweet potatoes, sesame seeds, almonds, and soy products. A vegan diet or one very low in animal products also is effective in preventing kidney stones, especially when combined with a very low salt diet.

People prone to form kidney stones may also be given medication to help prevent their formation. A thiazide diuretic can help prevent the formation of calcium stones. Allopurinol (Zyloprim, Aloprim) reduces the amount of uric acid blood and urine and helps prevent the formation of uric acid stones. Sturvite

WWW.BOOKBAZ.IR

KEY TERMS

Diuretic—A substance that removes water from the body by increasing urine production.

pH—A measure of the acidity of a fluid. On a scale of 1 to 14, a pH of 7 is neutral. Higher pH readings are alkaline and lower pH readings are acidic.

Ureter—A tube that carries urine from the kidney to the bladder.

stones often form when the kidney becomes infected, so preventing infection also helps to prevent stone formation. Cystine stones are difficult to prevent.

Kidney transplantation

Definition

Kidney transplantation is a surgical procedure to remove a healthy, functioning kidney from a living or brain-dead donor and implant it into a patient who is in the final stages of kidney failure.

Purpose

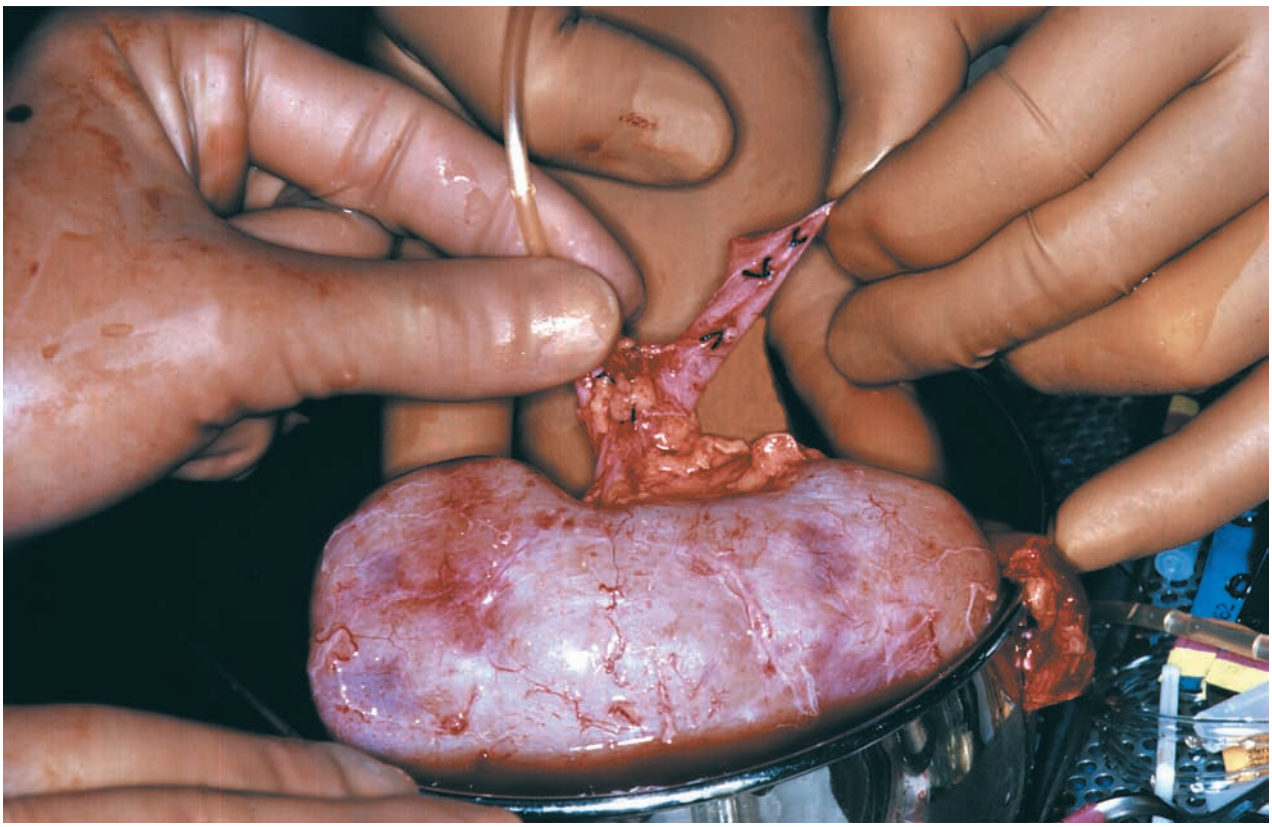
Kidney transplantation is performed on patients with **chronic kidney failure**, or end-stage renal disease (ESRD). ESRD occurs when a disease, disorder, or congenital condition damages the kidneys so that they are no longer capable of adequately removing fluids and wastes from the body or of maintaining the proper level of certain kidney-regulated chemicals in the bloodstream. Without long-term dialysis or a kidney transplant, ESRD is fatal.

Demographics

Diabetes mellitus is the leading single cause of ESRD. **Hypertension** (high blood pressure) is the second leading cause of ESRD in adults, followed by **glomerulonephritis**. African Americans are more likely to develop hypertension-related ESRD than Caucasians and Hispanics. People of Native American and Hispanic descent are at an elevated risk for both **kidney disease** and diabetes.

Among children and young adults under 20 on dialysis, glomerulonephritis is the leading cause of ESRD, followed by hereditary, cystic, and congenital diseases. According to USRDS, the average waiting period for a kidney transplant for patients under age 20 is 10 months, compared to the adult wait of approximately two years.

In mid-2013, there were 96,645 people awaiting kidney transplant in the United States. About 17,000 kidney transplants occur annually—nearly 12,000 from deceased donors and almost 6,000 from living donors. Every month, about 3,000 individuals are added to the kidney transplant waiting list. Unfortunately, about 13 people from that list die daily without ever having received their transplant. In a year, around 5,000 people die without making it to transplantation. Although African American, Hispanic, and Native American patients are more likely to go into end-stage renal failure, the percentage of live donors who are Caucasian far exceeds all other demographics (around 70%, with only 11% African American live donors and 13% Hispanic live donors).



A human kidney is being prepped by medical personnel prior to transplantation. *(Custom Medical Stock Photo, Inc.)*

Description

A kidney transplant is performed by a transplant surgeon in one of more than 200 UNOS-approved hospitals nationwide. If the patient has no living donor, he or she must go through an evaluation procedure to get on the UNOS national waiting list and the UNOS Organ Center's UNet database.

Kidney transplantation involves surgically attaching a functioning kidney, or graft, from a brain-dead organ donor (a cadaver transplant) or from a living donor to a patient with ESRD. Living donors may be related or unrelated to the patient, but a related donor has a better chance of having a kidney that is a stronger biological match for the patient.

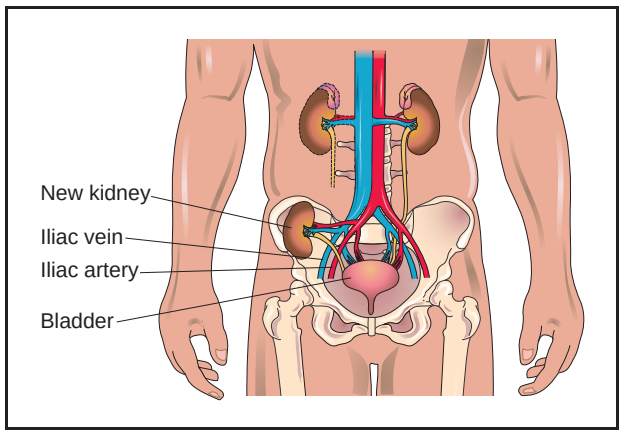
Open nephrectomy

The surgical procedure to remove a kidney from a living donor is called a **nephrectomy**. In a traditional, open nephrectomy, the kidney donor is administered general **anesthesia** and a 6–10 in (15.2–25.4 cm) incision through several layers of muscle is made on the side or front of the abdomen. The blood vessels connecting the kidney to the donor are cut and clamped, and the ureter is also cut and clamped between the bladder and kidney. The kidney and an attached section of ureter are removed from the donor. The vessels and ureter in the donor are then tied off and the incision is sutured together again. A similar procedure is used to harvest cadaver kidneys, although both kidneys are typically removed at once, and blood and cell samples for **tissue typing** are also taken.

Laparoscopic nephrectomy

Laparoscopic nephrectomy is a form of **minimally invasive surgery** using instruments on long, narrow rods to view, cut, and remove the donor kidney. The surgeon views the kidney and surrounding tissue with a flexible videoscope. The videoscope and surgical instruments are maneuvered through four small incisions in the abdomen, and carbon dioxide is pumped into the abdominal cavity to inflate it for an improved visualization of the kidney. Once the kidney is freed, it is secured in a bag and pulled through a fifth incision, approximately 3 in (7.6 cm) wide, in the front of the

WWW.BOOKBAZ.IR



Kidney transplantation involves the surgical attachment of a functioning kidney, or graft, from a donor to a patient with end-stage renal disease (ESRD). *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

abdominal wall below the navel. Although this surgical technique takes slightly longer than an open nephrectomy, studies have shown that it promotes a faster recovery time, shorter hospital stays, and less postoperative **pain** for kidney donors.

A modified laparoscopic technique called hand-assisted laparoscopic nephrectomy may also be used to remove the kidney. In the hand-assisted surgery, a small incision of 3–5 in (7.6–12.7 cm) is made in the patient's abdomen. The incision allows the surgeon to place his or her hand in the abdominal cavity using a special surgical glove that also maintains a seal for the inflation of the abdominal cavity with carbon dioxide. The technique gives the surgeon the benefit of using his or her hands to feel the kidney and related structures. The kidney is then removed through the incision by hand instead of with a bag. With newer robotic-assisted techniques, the surgeon directs the movement of tiny surgical instruments while seated at a computer console. This allows for a high degree of precision.

Once removed, kidneys from live donors and cadavers are placed on ice and flushed with a cold preservative solution. The kidney can be preserved in this solution for 24–48 hours until the transplant takes place. The sooner the transplant takes place after harvesting the kidney, the better the chances are for proper functioning.

Kidney transplantation

During the transplant operation, the kidney recipient is typically under general anesthesia and administered **antibiotics** to prevent possible infection. A catheter is placed in the bladder before surgery begins. An incision is made in the flank of the patient, and the surgeon implants the kidney above the pelvic bone and below the existing, non-functioning kidney by suturing the kidney artery and vein to the patient's iliac artery and vein. The ureter of the new kidney is attached directly to the kidney recipient's bladder. Once the new kidney is attached, the patient's existing, diseased kidneys may or may not be removed, depending on the circumstances surrounding the kidney failure. Barring any complications, the transplant operation takes about three to four hours.

Since 1973, Medicare has picked up 80% of ESRD treatment costs (after the patient meets the deductible), including the costs of transplantation for both the kidney donor and the recipient. Medicare also covers 80% of immunosuppressive medication costs for up to three years. To qualify for Medicare ESRD benefits, a patient must either have worked a certain number of hours to meet federal requirements, be receiving or eligible for benefits under Social Security, or be a spouse or child of an eligible American. Private insurance and state Medicaid programs often cover the remaining 20% of treatment costs. In the case of live donation, Medicare will pay the entire cost of caring for the donor.

Patients with a history of **heart disease**, lung disease, cancer, or hepatitis may not be suitable candidates for receiving a kidney transplant.

Preparation

Patients with chronic renal disease who need a transplant and do not have a living donor registered with United Network for Organ Sharing (UNOS) to be placed on a waiting list for a cadaver kidney transplant. UNOS is a nonprofit organization that is under contract with the federal government to administer the Organ Procurement and Transplant Network (OPTN) and the national Scientific Registry of Transplant Recipients (SRTR).

Kidney allocation is based on a mathematical formula that awards points for factors that can affect a successful transplant, such as time spent on the transplant list, the patient's health status, and age. The most important part of the equation is that the kidney be compatible with the patient's body. A human kidney has a set of six antigens, substances that stimulate the production of antibodies. (Antibodies then attach to cells they recognize as foreign and attack them.) Donors are tissue matched for 0–6 of the antigens, and compatibility is determined by the number and strength of those matched pairs. Blood type

KEY TERMS

Arteriogram—A diagnostic test that involves viewing the arteries and/or attached organs by injecting a contrast medium, or dye, into the artery and taking an x-ray.

Congenital—Of or relating to a condition that is present at birth, as a result of either heredity or environmental influences.

Dialysis—A blood filtration therapy that replaces the function of the kidneys, filtering fluids and waste products out of the bloodstream. There are two types of dialysis treatment: hemodialysis, which uses an artificial kidney, or dialyzer, as a blood filter; and peritoneal dialysis, which uses the patient's abdominal cavity (peritoneum) as a blood filter.

Glomerulonephritis—A disease of the kidney that causes inflammation and scarring and impairs the kidney's ability to filter waste products from the blood.

Iliac artery—Large blood vessel in the pelvis that leads into the leg.

Immunosuppressive medication—Drugs given to a transplant recipient to prevent his or her immune system from attacking the transplanted organ.

Rejection—The process in which the immune system attacks foreign tissue such as a transplanted organ.

Videoscope—A flexible surgical camera that produces video images comparable to that of a high-end camcorder.

matching is also important. Patients with a living donor who is a close relative have the best chance of a close match.

Before being placed on the transplant list, potential kidney recipients must undergo a comprehensive physical evaluation. In addition to the compatibility testing, radiological tests, urine tests, and a psychological evaluation will be performed. A panel of reactive antibody (PRA) is performed by mixing the patient's serum (white blood cells) with serum from a panel of 60 randomly selected donors. The patient's PRA sensitivity is determined by the number of random samples with which his or her serum reacts—for example, a reaction to the antibodies of six of the samples would mean a PRA of 10%. High reactivity (also called sensitization) means that the recipient would likely reject a transplant from the donor. The more reactions, the higher the PRA and the lower the chances of an overall match from the general population. Patients with a high PRA face a much longer waiting period for a suitable kidney match.

Potential living kidney donors also undergo a complete medical history and **physical examination** to evaluate their suitability for donation. Extensive blood tests are performed on both donor and recipient. The blood samples are taken to analyze tissue types for antigen matches and confirm blood types for compatibility. A PRA is performed to ensure that the recipient antibodies will not have a negative reaction to the donor antigens. If a reaction does occur, there are some treatment protocols that can be attempted to reduce reactivity, including **immunosuppressant drugs** and **plasmapheresis** (a blood filtration therapy).

The donor's kidney function will be evaluated with a urine test as well. In some cases, a special dye that shows up on x-rays is injected into an artery, and x-rays are taken to show the blood supply of the donor kidney (a procedure called an arteriogram).

Once compatibility is confirmed and the physical preparations for kidney transplantation are complete, both donor and recipient may undergo a psychological or psychiatric evaluation to ensure that they are emotionally prepared for the transplant procedure and aftercare regimen.

Aftercare

A typical hospital stay for a transplant recipient is about five days. Both kidney donors and recipients will experience some discomfort in the area of the incision after surgery. Pain relievers are administered following the transplant operation. Patients may also experience numbness, caused by severed nerves, near or on the incision.

A regimen of immunosuppressive, or anti-rejection, medication is prescribed to prevent the body's immune system from rejecting the new kidney. Common immunosuppressants include cyclosporine, prednisone, tacrolimus, mycophenolate mofetil, sirolimus, basiliximab, daclizumab, and azathioprine. The kidney recipient will be required to take a course of immunosuppressant drugs for the lifespan of the new kidney. Intravenous antibodies may also be administered after **transplant surgery** and during rejection episodes.

Because the patient's immune system is suppressed, he or she is at an increased risk for infection. The incision area should be kept clean, and the transplant recipient should avoid contact with people who have colds, viruses, or similar illnesses. If the patient has pets, he or she should not handle animal waste. The transplant team will provide detailed instructions on

what should be avoided post-transplant. After recovery, the patient will still have to be vigilant about exposure to viruses and other environmental dangers.

Transplant recipients may need to adjust their dietary habits. Certain immunosuppressive medications cause increased appetite or **sodium** and protein retention, and the patient may have to adjust his or her intake of calories, salt, and protein to compensate.

Results

The new kidney may start functioning immediately, or it may take several weeks to begin producing urine. Living donor kidneys are more likely to begin functioning earlier than cadaver kidneys, which frequently suffer some reversible damage during the kidney transplant and storage procedure. Patients may have to undergo dialysis for several weeks while their new kidney establishes an acceptable level of functioning.

Studies have shown that after they recover from surgery, kidney donors typically have no long-term complications from the loss of one kidney, and their remaining kidney will increase its functioning to compensate for the loss of the other.

Risks

As with any surgical procedure, the kidney transplantation procedure carries some risk for both a living donor and a graft recipient. Possible complications include infection and bleeding (hemorrhage). A lymphocele, a pool of lymphatic fluid around the kidney that is generated by lymphatic vessels damaged in surgery, occurs in up to 20% of transplant patients and can obstruct urine flow and/or blood flow to the kidney if not diagnosed and drained promptly. Less common is a urine leak outside of the bladder, which occurs in approximately 3% of kidney transplants when the ureter suffers damage during the procedure. This problem is usually correctable with follow-up surgery.

A transplanted kidney may be rejected by the patient. Rejection occurs when the patient's immune system recognizes the new kidney as a foreign body and attacks the kidney. It may occur soon after transplantation or several months or years after the procedure has taken place. Rejection episodes are not uncommon in the first weeks after transplantation surgery and are treated with high-dose injections of immunosuppressant drugs. If a rejection episode cannot be reversed and kidney failure continues, the patient will typically go back on dialysis. Another transplant procedure can be attempted at a later date if another kidney becomes available.

The biggest risk to the recovering transplant recipient is not from the operation or the kidney itself, but from the immunosuppressive medication he or she must take. Because these drugs suppress the immune system, the patient is susceptible to infections such as cytomegalovirus (CMV) and varicella (**chickenpox**). Other medications that fight viral and bacterial infections can offset this risk to a degree. The immunosuppressants can also cause a host of possible side effects, from high blood pressure to **osteoporosis**. Prescription and dosage adjustments can lessen side effects for some patients.

Survival rates for patients undergoing kidney transplants are about 97% one month post-transplant, 94% one year after transplant, and about 85% three years after transplant. The success of a kidney transplant graft depends on the strength of the match between donor and recipient and the source of the kidney. Transplantations using living donor kidneys have a higher rate of success than do cadaver kidney transplantations.

Alternatives

Patients who develop chronic kidney failure must either go on dialysis treatment or receive a kidney transplant to survive.

Kidney ultrasound *see* **Abdominal ultrasound**

Kidney, ureter, and bladder x-ray study

Definition

A kidney, ureter, and bladder (KUB) x-ray study is an abdominal x ray. Despite its name, KUB does not show the ureters and only sometimes shows the kidneys and bladder and, even then, with uncertainty.

Purpose

The KUB study is a diagnostic test used to detect **kidney stones** and to diagnose some gastrointestinal disorders. The KUB is also used as a follow-up procedure after the placement of devices such as ureteral stents and nasogastric or nasointestinal tubes (feeding tubes) to verify proper positioning.

An x-ray image of a human torso and abdomen showing a blocked ureter. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

KEY TERMS

Ureteral stent—A surgical device implanted in patients with damaged ureters that holds the ureter open so that urine can flow freely from the kidneys to the bladder.

Precautions

Because of the risks of radiation exposure to the fetus, pregnant women are advised to avoid this x-ray procedure.

A KUB study is a preliminary screening test for kidney stones, and should be followed by a more sophisticated series of diagnostic tests (such as an **abdominal ultrasound**, **intravenous urography**, or computed tomography scan [CT scan]) if kidney stones are suspected.

Description

A KUB is typically a single x-ray procedure. The patient lies flat on his back on an x-ray table. An x-ray plate is placed underneath him near the small of the back, and the x-ray camera is aimed at his abdomen. The patient is asked to hold his breath and lie still while the x ray is taken. Sometimes a second KUB will be ordered, with the patient standing, or if unable to do so, lying on his side.

Preparation

A KUB study requires no special diet, fluid restrictions, medications, or other preparation. The patient is typically required to wear a hospital gown or similar attire and to remove all jewelry so the x-ray camera has an unobstructed view of the abdomen. A lead apron may be placed over the abdominal areas of the body not being x-rayed to shield the patient from unnecessary radiation.

Aftercare

No special aftercare treatment or regimen is required for a KUB study.

Results

Normal KUB x-ray films show two kidneys of a similar size and shape. A normal amount of intestinal gas is seen.

Abnormal results

Abnormal KUB films may show calculi (kidney stones). If both kidneys are visible, it may be possible to diagnose renal size discrepancies. The films may also show too much bowel gas indicating possible obstruction or soft tissue masses.

Risks

Because the KUB study is an x-ray procedure, it does involve minor exposure to radiation.

Kinesiology, applied

Definition

Kinesiology is a series of tests that locate weaknesses in specific muscles reflecting imbalances throughout the body. Then specific massages or **acupressure** techniques are used in an attempt to rebalance what has been revealed by the kinesiology tests. Thus, kinesiology is used as both an assessment tool and as a limited therapeutic modality.

Purpose

Kinesiology claims to be a healing system that detects and corrects imbalances in the body before they develop into a disease, and which restores overall system balance and harmony. It is used to alleviate muscle, bone, and joint problems, treat all manner of aches and pains, and correct many areas of imbalance and discomfort.

Precautions

Since interpretation of the muscle tests is both complex and subjective, it should only be performed by a licensed health professional trained to look for "subclinical" symptoms (those which have not yet become a major problem). Kinesiology, itself, is more of a diagnostic technique and should not be thought of as a cure for any particular problem.

Description

Traditionally, the word "kinesiology" refers simply to the study of muscles and body movement. In 1964, however, American chiropractor George J. Goodheart founded what has become known as applied kinesiology when he linked oriental ideas about energy flow in the body with western techniques of muscle testing. First, Goodheart noted that all muscles are related to other muscles. He observed that for each movement a muscle makes, there is another muscle or group of muscles involved with that movement; one muscle contracts while another one relaxes. So when he was presented with a painful, overly-tight muscle, he would observe and treat the opposite, and necessarily weak, muscle to restore balance. This was then a very new technique.

Further, Goodheart argued that there is a definite and real connection between muscles, glands, and organs, and that by testing the strength of certain muscles he could learn about the health or condition of the gland or organ to which it was related.

Applied kinesiology is based on the idea that the body is an interacting unit made of different parts that interconnect and affect each other. Everything we do affects the body as a whole; therefore, a problem in one area can cause trouble in another area. According to kinesiology, the muscles eventually register and reflect anything that is wrong with any part of the body, whether physical or mental. Thus, a particular digestive problem might show up in the related and corresponding muscles of the legs. By testing the strength of certain muscles, the kinesiologist claims to be able to gain access to the body's communication system, and, thus, to read the health status of each of the body's major components.
